Additional fundamental requirements for the diffractometer are low backgrounds, stable detectors and detector electronics, stable beam monitors and a stable moderator. The low backgrounds are achieved primarily by excellent collimation and shielding, including a well shielded primary-beam dump, or 'get lost tube'. These modern instruments produce huge amounts of data requiring specialized data-reduction programs, which are well developed at this point, for example, *PDFgetN* (Peterson *et al.*, 2000) and *Gudrun* (Soper & Barney, 2011). Tools are also being developed as part of the Mantid project (http://mantid-project.org).

Diffractometers at reactor sources work quite differently. By way of example, D4 at ILL (Fischer *et al.*, 2002), on a hot moderator source, has a standard wavelength of 0.5 Å and detector banks cover a range from 2 to 140° that yields PDFs with $Q_{\max}$ = 23.6 Å^{-1}. Of particular interest at D4 is the very low background due to tight secondary collimation (after the sample and before the detectors). It was designed in part for detecting small differences in isotope-substitution measurements of glasses and liquids. To do this successfully, it is important to have extremely good count-rate stability and low backgrounds.

5.7.3.2. *X-rays*

Excellent PDFs may be obtained from nanomaterials using X-rays and this has become a widely used technique. Historically, PDFs with modest $Q_{\max}$ were obtained from laboratory sources with Mo or Ag sources. High real-space resolution PDFs were not thought to be feasible, even from higher-energy X-ray sources where the higher $Q_{\max}$ could be accessed, because the X-ray signal is strongly attenuated in this high-Q region because of the atomic form factor. This is indeed true, and neutrons are often preferred for high real-space resolution work for this reason. However, with the advent of high-energy synchrotron sources that produce an abundance of hard X-rays, it was demonstrated that sample-limited resolutions could be obtained even for quite challenging covalently bonded samples (Petkov *et al.*, 1999; Laaziri *et al.*, 1999; Petkov *et al.*, 2000; Jeong, Mohiuddin-Jacobs *et al.*, 2001). The experiments were slow and arduous, but with the advent of the rapid acquisition PDF (RAPDF) method (Chupas *et al.*, 2003) that utilizes two-dimensional (2D) detectors and a very high energy X-ray source, obtaining PDFs from X-rays has become straightforward and much more accessible.

Synchrotron sources with an electron energy of around 2.4 GeV or greater are preferred for PDF work on crystals and nanocrystals. The newer 'third-generation' sources such as the European Synchrotron Radiation Facility (ESRF) (Grenoble, France, http://www.esrf.eu/), the Advanced Photon Source (APS) (Argonne National Laboratory, Illinois, USA, http://www.aps.anl.gov/), SPRING-8 (Harima, Japan, http://www.spring8.or.jp/), NSLS-II (Brookhaven National Laboraotry, New York, USA, http://www.bnl.gov/ps/), Diamond Light Source (Rutherford Appleton Laboratory, Oxfordshire, UK, http://www.diamond.ac.uk/), Soleil (Saclay, France, http://www.synchrotron-soleil.fr/), PETRA-III (DESY Lab, Hamburg, http://petra3.desy.de/), MAX-IV (Sweden) and so on, feature high luminosity in addition to high intensity at high X-ray energies. Many scattering experiments that were formerly impossible or impractical are now feasible. Growth of the PDF technique has led to a number of beamlines operating or under construction at these sources that are optimized for PDF measurements, including at the time of writing, 11IDB and C at APS, XPD at NSLS-II, ID11 and ID15 at ESRF and XPDF at Diamond, although these designations tend to change with time because of facility upgrades and new construction. Current statuses can be found at facility websites. Good PDFs can also be obtained from laboratory X-ray sources with Mo or Ag anodes. The tradeoff is a significant reduction in intensity, which results in very long measurement times.

The primary respect in which modern synchrotron sources have revolutionized the PDF method is through the use of the RAPDF method, which is illustrated schematically in Fig. 5.7.8 and is extremely straightforward.

High-energy monochromatic X-rays from a synchrotron source are incident on the sample. A large-area 2D detector is placed orthogonal to the beam, in transmission geometry, and as close behind the sample as possible. The full diffraction pattern can be collected in a single frame that may be as short as around 30 ms. More often, multiple frames are collected with an integrated exposure time of a few seconds to a few minutes to get quality data to high Q. The geometry of the sample is sometimes pill-shaped and sometimes a capillary. The preferred diameter of the sample capillary or thickness of the pill depends on the scattering power of the sample for the incident X-ray energy. Normally 1 mm internal diameter (ID) capillary tubes are loosely filled with powder and mounted on a goniometer head or other support. For weakly scattering samples such as organics it may be preferable to use 2 mm ID tubes to increase the scattered intensity, albeit with a somewhat lower Q resolution of the measurement. For ease of handling and relatively weak scattering power, capillaries made of polyimide (sometimes called Kapton) tubing are often used. High-energy X-rays are very penetrating and it is rarely necessary to adjust the tube diameter to minimize absorption effects, although to increase the scattering signal from weakly scattering samples it is sometimes desirable to use larger diameter tubes, and to increase the Q-space resolution for strongly scattering samples it is possible to use smaller diameter samples too.

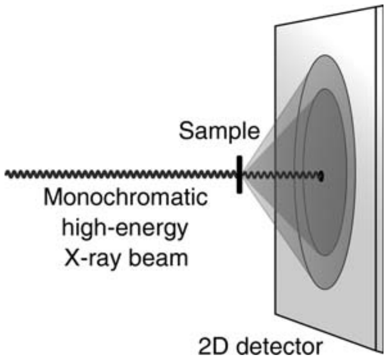

Figure 5.7.8
Schematic of the 2D detector and sample placement for a typical RAPDF measurement.

The capillary is often mounted with its long axis perpendicular to the beam, but may be mounted vertically or horizontally or at any other orientation, since the sample itself is an isotropic powder of micro- or nanograins. The final choice of orientation of the capillary will then depend on optimizing many experimental factors such as beam or measurement geometry or sample environment. Because of the horizontal polarization of the electric field of the X-rays at synchrotron sources, the detector is often scanned in the vertical plane when data are collected over a wide angular range. In this case a horizontal orientation of the capillary is more natural. The incident beam is often rectangular, or elongated in the horizontal plane if the source is a bending magnet or wiggler, and again a horizontal orientation may be preferred. Expediencies such as the best way to cool a sample with a flowing nitrogen cooler or a cramped environment in the instrument hutch at the sample position can all also affect the choice of orientation.

Overall, the RAPDF method is well adapted to experiments in special environments such as high temperature, high pressure, magnetic field or controlled gas environments. However, if a PDF over wide ranges of r is desired, then a higher Q-resolution measurement than is possible in the RAPDF geometry is needed. Similarly, if the X-ray energy is limited to a value much below 30 keV, for example when working at the absorption edge of low or intermediate Z or if using an Mo or Ag laboratory X-ray source, the available Q range in the RAPDF experiment will be very low and the RAPDF geometry is not preferred. In these cases the old-fashioned scanned-point-detection scheme, or a wide-angle 1D detector such as a strip detector, may be utilized. The experimental geometry could be Debye–Scherrer or Bragg–Brentano (Klug & Alexander, 1974). Roughly speaking, any powder-diffraction measurement carried out to sufficiently high Q can be used for a PDF measurement. One example is the high-

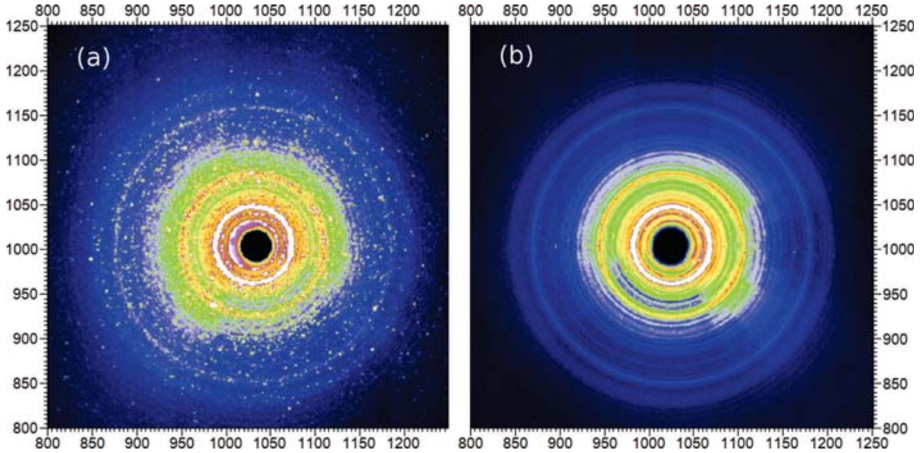

Figure 5.7.9
An example of the better powder average (reduced spottiness of the diffraction pattern) obtained when a sample with a poor powder average is spun. (*a*) Measured without spinning and (*b*) with spinning the capillary. The sample was a crystalline small-molecule organic sample.

resolution powder diffractometer currently at ID22 at ESRF, which has a bank of multiple analyser crystals (Fitch, 2004). It is mostly used for high-resolution powder diffraction for crystallographic analyses, but can also be used to good effect for PDF studies because the beamline can be operated with quite short wavelength X-rays. No special setup is required, but care should be taken to count for a long time in the high-angle region. Exactly how long is something that has to be assessed on a trial-and-error basis. It can be misleading to look at the counting statistics in individual bins in the high-Q region alone, since this depends on the bin width and the Fourier transform sums bins. In fact, the best way to assess this is to propagate the data all the way to the PDF, determine the $Q_{\max}$ that is desired and see whether the resulting PDF has a sufficient signal:noise ratio, then go back and count for longer if needed. Once this has been done for a particular experimental setup, it is then possible to judge directly by looking at the Q-space data. The high-resolution results in PDFs extend very far in r space, up to hundreds of nanometres for well ordered samples.

In terms of sample preparation for crystalline samples, the particle size should be small (<40 µm) and uniform. This may be accomplished by careful grinding in a mortar and pestle and sieving the sample through a 400 mesh sieve. Smaller particle sizes may be obtained by using a mechanical ball mill. This is particularly important to avoid spotty data. It can also help to reduce preferred orientation of grains (sometimes called texture) in the sample. It is less relevant for nanoparticulate samples that do not have large coherently scattering grains. Special difficulties can arise if the powder grains have a particularly oblate or prolate morphology. Oblate grains are generally not a problem in capillaries, but needle-like grains can become significantly orientationally ordered in a capillary if the sample size is too big. Gentle grinding often takes care of the problem, but samples containing needle-like grains could also be measured in the pill-shaped sample geometry described above to mitigate this problem.

Samples with crystallites that are too large produce ‘spotty’ diffraction patterns, which are easy to detect in a 2D diffraction pattern on an area detector (Fig. 5.7.9*a*). To mitigate this one can spin the capillary about its long axis, oriented perpendicular to the beam, which greatly improves powder statistics (Fig. 5.7.9*b*). In some sample environments spinning is not an option, but it may still be possible to wobble the sample, or gently rock it. Do so through as large an angular range as possible, but even a ±2° wobble during each exposure can help to improve the powder statistics a lot.

If the diffraction pattern from the spun or rocked sample is still spotty, it may be still be possible to recover a reasonably accurate PDF. For example, the 2D-to-1D integration also helps to average the intensity around the ring and the mean intensity of the spotty ring may not be so far from the ideal value. If a relatively small number of very bright spots are present within a more uniform ring of intensity it is possible to remove them by masking, or by taking the median intensity around the ring rather than the mean intensity during the integration step, which down-weights the contributions of the intense outlier spots. Of course it is better to remove the spottiness by better sample preparation where possible, as this removes uncertainty about how well the ‘work-around’ is working.

Loose powders may also be mounted in different geometries, such as in pill form supported with thin Kapton tape over the bottom and top surfaces. The Kapton tape is particularly important if the sample is to be cooled in a vacuum. Samples to be cooled may also be in Kapton capillaries. Uncovered powders rarely survive the pump down as air trapped between the grains forces its way out. Differential thermal contraction between the sample holder and the powder itself can also loosen a tightly packed powder. A small amount of grease, or Duco cement mixed with acetone, can also be mixed with a loose powder to stabilize it if the sample does not have to be recovered in its pristine state after the experiment. The scattering from the stabilizing agent is relatively weak and may be ignored in the subsequent data reduction in most cases.

5.7.3.3. *Electrons*

Some progress has been made recently in obtaining quantitatively reliable PDFs from electron-diffraction data measured on widely available laboratory electron microscopes. We refer to this electron-PDF as ePDF (Abeykoon *et al.*, 2012; Gorelik *et al.*, 2015) to differentiate from X-ray (xPDF) and neutron (nPDF) measurements. Application of ePDF methods to nanostructure determination is a relatively new development and practices and methods are likely to develop with time. However, we briefly describe here some aspects of the measurements that are pertinent for obtaining quantitative PDFs from nanosystems. An example of ePDF measurements from gold nanoparticles is shown in Fig. 5.7.10.

Apart from the strong scattering that leads to dynamical-scattering effects that distort the kinematical diffraction pattern needed for PDF work, electrons lend themselves naturally to a PDF analysis. Because of the strong scattering, a reasonable signal can be obtained from a small volume of sample in a very short time (*e.g.* 0.05 s). The study of amorphous thin films using electrons dates back to the pioneering work of Moss & Graczyk (1969) on amorphous silicon. Following this, a number of researchers collected similar data on amorphous thin films using energy filtering and various electron-detection methods

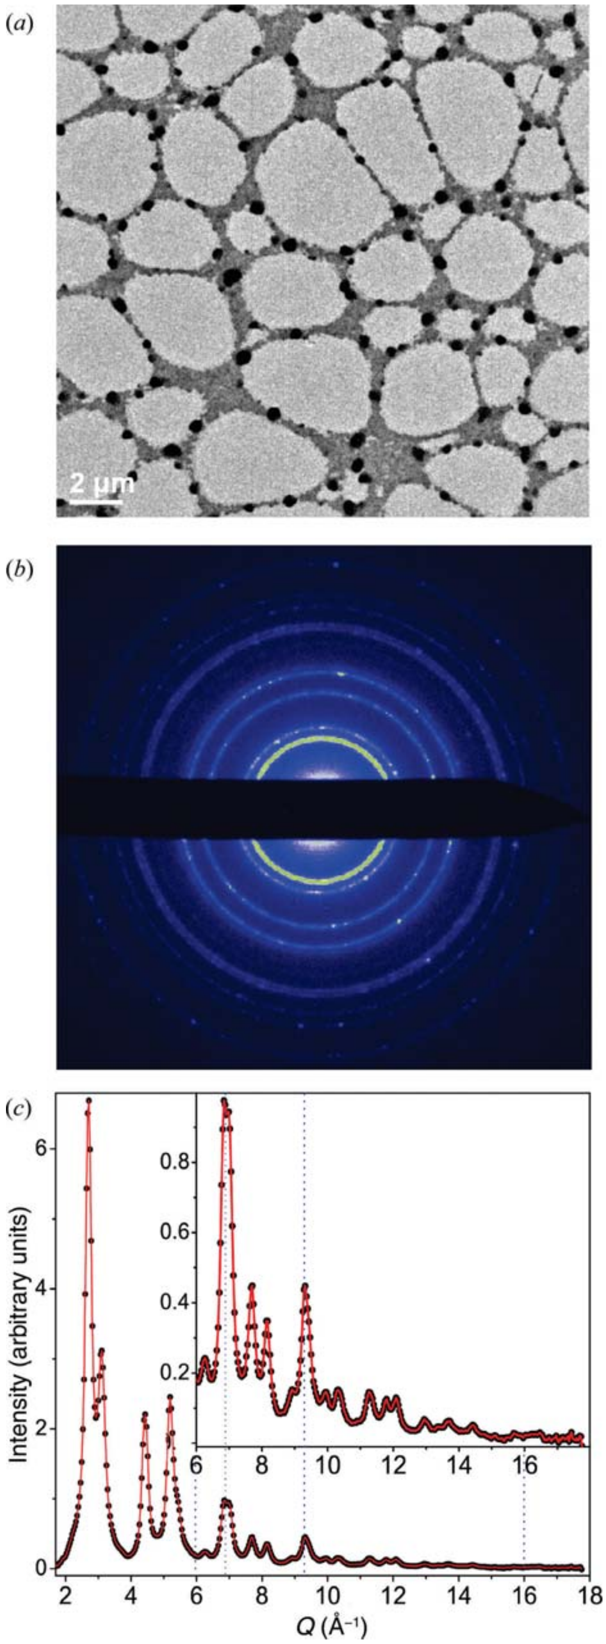

Figure 5.7.10
(*a*) TEM image of 100 nm Au nanoparticles (black dots) used for ePDF measurement. (*b*) Background-subtracted ED image of same region collected using 200 keV electrons. (Chaudhari *et al.*, 1972; Rudee & Howie, 1972; Gandais *et al.*, 1973; Cockayne & McKenzie, 1988; McBride *et al.*, 1999). Recently it has been shown that PDFs from nanomaterials can be obtained using electron diffraction that are sufficiently quantitatively reliable that they may be modelled using PDF modelling programs such as *PDFgui* (Abeykoon *et al.*, 2012). This study demonstrated the possibility of obtaining quantitatively accurate PDFs using standard laboratory transmission electron microscopes.

When collecting data for ePDF measurements, some issues require more careful consideration than for X-ray or neutron powder-diffraction measurements. Samples must be thin enough to avoid too much multiple scattering. For example, nanoparticles and films below 10 nm thickness are ideal. Because of the small sample volumes care must be taken to obtain a good powder average, which may be accomplished by taking multiple diffraction patterns from different parts of the sample, or rocking the sample. The camera length should typically be as short as possible. This may be set by adjusting electron-lens currents (Abeykoon *et al.*, 2015). A calibration of the camera length may be made by measuring a calibration sample of known lattice parameter. It is important to carry out the calibration measurements under precisely the same conditions, including all the lens currents, as the experiment on the sample itself. ePDFs may be collected using a standard CCD camera, although under certain circumstances an image plate may be preferred. The sample is usually supported on a weakly scattering membrane such as a holey carbon grid. The signal from the background may be measured from a region of the sample holder that contains no nanoparticles or film in the field of view. The use of an energy filter was at first thought to be essential, but has since been shown not to be (Abeykoon *et al.*, 2012). The perennial problem in electron diffraction, beam damage, is also true for ePDF but is manageable if handled correctly (Gorelik *et al.*, 2015).

5.7.3.4. *Q ranges and Q resolutions*

We briefly compare here the ranges of Q and the Q resolutions of these different sources and data-collection methods. Just to recap, collecting data over a wide Q range results in sharp peaks in the PDF and a high real-space resolution, at least from well ordered samples. On the other hand, the Q-space resolution affects the range in r over which the PDF extends. A lower-resolution measurement results in the PDF being attenuated by a resolution 'envelope' that diminishes the amplitude of the PDF peaks with increasing r. This is similar to the effects of nanocrystallinity. One should select the measurement geometry and source type that results in the best compromise of these factors (taking into account access to instrumentation, speed of measurement, penetration of special environments and so on) to extract the desired scientific result.

Historically, time-of-flight neutrons have been the probe of choice for the highest accuracy PDFs. At modern instruments PDFs can be collected over wide ranges of Q and with medium Q-space resolution, but adequate to get signals to hundreds of ångstroms in real space from well ordered samples. Neutrons also have the advantage that stronger peaks can be obtained from low-atomic-number materials, even when they are in a structure with high-atomic-number materials. The principal drawbacks are the large samples that are needed for neutron studies (typically grammes, although much smaller samples can now be studied with modern instruments), the relatively slow measurement times (typically hours per data set, although this is reduced to fractions of hours at modern sources) and the difficulty of accessing neutron beamtime due to oversubscription of the few available instruments. The principal advantages of RAPDF X-ray experiments at modern sources are the rapidity with which the data can be collected and the small sample sizes. Access to RAPDF X-ray instruments through general user programs can be limited, although this tends to be a less serious problem than for neutron instruments, which are more oversubscribed in general. In this geometry the Q resolution is low, which means even the most beautiful well ordered crystal appears nanocrystalline. The 'instrument resolution' damping can be corrected in modelling by calibrating against a well ordered sample measured in the same geometry, so this is not an insurmountable problem, but it means that the data are less accurate at determining the size and shape of the (coherent core of) the particles than higher Q-resolution data. However, a number of factors make the RAPDF approach currently the most widely used and most rapidly growing data-collection method. The ease of the experiments, small amount of sample that is required and high throughput (data can be collected in seconds, or less in favourable circumstances) make it a straightforward way to get high-quality PDFs. The open sample position coupled with the high energy of the incident X-rays also make this geometry straightforward for developing experiments in special environments such as low and high temperature, high pressure, and *in situ* reaction and flow cells. Such experiments can be done at neutron sources too, but are more difficult to engineer because of the relative inaccessibility of the sample position.

It is rare that information in PDFs is desired from the very high r region, but when it is, the highest Q-resolution measurements, and therefore PDFs extending over the highest range in r, can be obtained from high-resolution X-ray powder diffraction setups that nonetheless have a high incident X-ray energy. Examples are ID22 at the ESRF (formerly ID31) and XPD at NSLS-II, which may be used in RAPDF or high-resolution geometries. In high-resolution geometry data collection can be very slow, with one data set taking many hours to collect. This is not warranted unless data extending to high r are desired.

If a laborartory powder diffractometer with good flux and an Mo or Ag source is available, PDF experiments can be carried out using laboratory X-ray equipment. The great advantage of this is ease of access to the instrument: the user does not have to wait for access to a beamline through a slow proposal process. However, the data collection is much slower than in the RAPDF geometry and it can take an hour to many hours per data set, depending on the Q range of the measurement.

Finally, we mention ePDF, which is still under active development. This promises to be a very good way to obtain semi-quantitative PDFs very rapidly from very small amounts of sample on instruments that many laboratories have access to. We expect that this will become a powerful approach for quickly obtaining data from large numbers of samples, for example when screening samples during synthesis. Promising samples may then be subjected to more accurate xPDF and nPDF methods.

5.7.4. Data reduction

A detailed description of the processes for obtaining accurate PDFs from neutron, X-ray and electron diffraction data are beyond the scope of this chapter. Interested readers are referred to Chapter 5 of the book by Egami & Billinge (2012). The steps take a raw powder-diffraction pattern from an experiment, extract the coherent scattering cross section of the material and then correctly normalize it to absolute units (usually per atom) to obtain $S(Q)$, then $F(Q)$ and finally $G(r)$ as described in Section 5.7.2. Extra sources of scattering include scattering from a sample holder and other experimental components, air scattering, multiple scattering (*i.e.*, intensity from particles that have been scattered twice before reaching the detector), incoherent Compton scattering and fluorescence in the case of X-rays, and so on. There are also multiplicative aberrations to the data due to such things as sample absorption, detector response function *etc*. There are widely available computer programs for carrying out these tasks (Juhás *et al.*, 2013; Soper & Barney, 2011; Qiu *et al.*, 2004; Petkov, 1989; Jeong, Thompson *et al.*, 2001; Peterson *et al.*, 2000).

When attempting to extract coordination numbers directly from the data, or if modelling is to be carried out on an absolute scale, it is necessary to carry out an absolute normalization of the data, which is possible but requires care. The incident flux, the actual density of the sample powder or compress, the volume of the sample probed and so on must be known. It is more straightforward to do this from neutron-scattering data by the use of both upstream and downstream beam intensity monitors and comparing the loss in intensity with an incoherently scattering calibration sample, which may be a bar of vanadium (or, to be completely incoherently scattering, a vanadium–niobium alloy) of known dimension and density. It is much more difficult in the case of X-rays, where there is no such incoherently scattering calibration sample available. In this case, a careful measurement of the absorption of the sample, μt, where μ is the linear absorption coeffcient of the sample and t its thickness, using ion-chamber detectors before and after the sample can help a lot. μt may also be determined approximately from theoretical considerations, since values of μ are tabulated in *International Tables for Crystallography* Volume C, Table 4.2.4.3 for each element, and the thickness and powder packing fraction can be estimated. The values of μ depend on the X-ray energy and the value corresponding to the incident X-ray energy should be used. More details can be found in Egami & Billinge (2012). It is often not necessary to place the data onto an absolute scale, since an overall scale factor can be applied to any PDF calculated from a structural model when comparing it to the data.

The scattering functions $S(Q)$, $F(Q)$ and $G(r)$ have characteristic asymptotic properties that aid with the data-normalization process. In particular, $S(Q)$ approaches unity asymptotically in the high-Q range, and at $Q = 0$ becomes approximately equal to zero [in fact $S(0) = 1 - \langle Z^2\rangle / \langle Z\rangle^2$, where $\langle Z\rangle$ is the sample average of the number of electrons of each ionic species, which is often taken as the atomic number]. One of the normalization steps is to divide the diffraction data by the square of the mean scattering factor, $\langle f(Q)\rangle^2$. This division is done after additive contributions to the signal, such as sample container, fluorescence and Compton scattering, have been properly removed. Because of the asymptotic behaviour of $S(Q)$ in the high-Q regime, correction factors such as the powder packing fraction, sample volume and so on can be adjusted in an iterative way until this normalization works correctly, resulting in an $S(Q)$ that approaches one asymptotically at high Q. Most X-ray data-reduction programs allow for this kind iterative updating (Qiu *et al.*, 2004; Soper & Barney, 2011; Petkov, 1989; Jeong, Thompson *et al.*, 2001), and some automate it to some extent.

There is a good separation in frequency between the signal from the sample and the unwanted parasitic scattering, and it has recently been shown that a completely *ad hoc* approach can be taken for data corrections (Billinge & Farrow, 2013) in many cases whereby the aberrations in the data are determined automatically and removed without inputting information about their origin. This has resulted in a fully automated X-ray data-reduction program, *PDFgetX3* (Juhás *et al.*, 2013), which has been shown to produce PDFs of comparable quality to one of the established programs that implements all the corrections explicitly, *PDFgetX2* (Qiu *et al.*, 2004). This approach does not result in a PDF on an absolute scale, which is generally not a problem when modelling the data since an overall scale factor can be applied to the calculated PDF. In practice, our experience is that data sets collected at the same time (for example, a temperature series) and processed using *PDFgetX3* all appear with the same scale factor and features such as peak heights can be compared with each other even without modelling.

5.7.5. Extracting structural information

5.7.5.1. *Obtaining the PDF from a model*

Assume that we have a model for our sample that consists of a set of N atoms at positions $\mathbf{r}_i$ with respect to some origin. The model is built up as described in Section 5.7.2.2.

If we consider a crystalline single-element material, for example nickel, a typical neutron-sized sample contains in the vicinity of 10^{20} or more atoms. To properly calculate $R(r)$ we would therefore need to carry out a double sum over this many atoms, which is completely impractical. However, in practice accurate PDFs can be calculated from many fewer (and a practically small number of) atoms. First, we are generally only interested in calculating $R(r)$ over a relatively narrow range of r, say 20 Å. In this case, we would still need to put the origin on each of the 10^{20} atoms in turn to accurately represent the sample, but each time the sum need only be taken over atoms that lie within 20 Å of the origin atom, a volume that contains only 10^2–10^3 atoms. Second, the material in question may be crystalline. In this case, the total sample is made up of many equivalent unit cells which are periodically repeated in space (although it should be noted that in real crystals, the ideal of every unit cell being identical may not hold well). In this favourable situation we need only place the origin on each atom in the unit cell, since the equivalent atom in all the other unit cells has exactly the same atomic environment. This is now a computationally tractable problem: a double sum where the first sum is taken over the atoms in the unit cell (typically <100) and the second sum over all atoms within $r_{\max}$ of the origin atom, where $r_{\max}$ is the maximum extent over which the PDF is to be calculated. This is shown in Fig. 5.7.11.

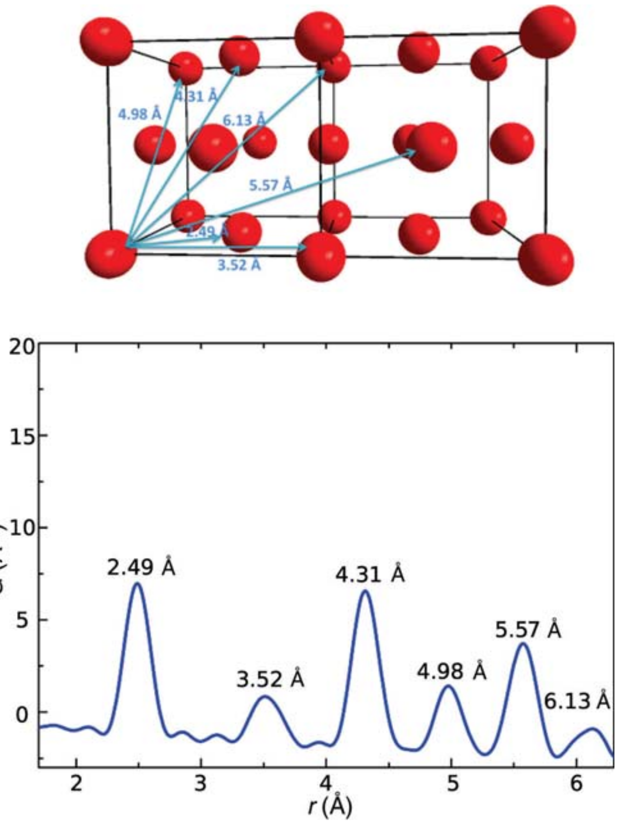

Figure 5.7.11
A schematic of the buildup of the PDF from the structural model for face-centred-cubic nickel. The top figure shows the bond distances of nearby atoms from a reference Ni atom at the corner. Its corresponding PDF is shown below.

Even in the case where the sample is nanocrystalline or amorphous, sufficient averaging over different possible configurations to replicate the measured PDF is in general possible with a much smaller number of atoms. For example, in typical big-box modelling approaches such as reverse Monte Carlo, boxes containing $\sim 10^4$ atoms are typical.

5.7.5.2. *PDFs from multi-element material*

When calculating the PDF from samples with multiple atomic species, we need an expression for the calculated radial distribution function expressed in terms of partial radial distribution functions between different atom types. In analogy to Section 5.7.2.6, when multiple elements are present in the sample we can write

$$\begin{aligned} R(r) &= \frac{1}{N\langle f\rangle^2}\sum_{i,j(i\neq j)} f_j^* f_i \delta(r-r_{i,j}) \\ &= \frac{1}{\langle f\rangle^2}\sum_{\alpha,\beta}\sum_{i\in\{\alpha\},j\in\{\beta\}(i\neq j)} \frac{f_\alpha^* f_\beta}{N}\delta(r-r_{i,j}) \\ &= \sum_{\alpha,\beta}\frac{c_\alpha c_\beta f_\alpha^* f_\beta}{\langle f\rangle^2}\left(\sum_{a,b}\frac{1}{Nc_\alpha c_\beta}\delta(r-r_{i,j})\right) \\ &= \sum_{\alpha,\beta}\frac{c_\alpha c_\beta f_\alpha^* f_\beta}{\langle f\rangle^2} R_{\alpha\beta}, \qquad (5.7.63) \end{aligned}$$

which serves to define

$$R_{\alpha\beta} = \frac{1}{Nc_\alpha c_\beta}\sum_{a,b}\delta(r-r_{i,j}). \qquad (5.7.64)$$

5.7.5.3. *Model-independent information from the PDF*

It is clear from this description that the PDF is a heavily averaged representation of the structure. First, directional information is lost. Second, it is a linear superposition of the local environments of many atoms. How can such a function contain any useful information at all? The reason is that, especially on very short length scales, the possible environments of particular atoms are very limited. In nickel, for example, all the atoms have the same number of neighbours (12) at the same nearest-neighbour distance, $r_{\rm nn}$ = 2.49 Å (Wyckoff, 1967). There is no intensity in $R(r)$ for $r < r_{\rm nn}$ and a sharp peak at $r_{\rm nn}$. This behaviour is very general and true even in atomically disordered systems such as glasses, liquids and gases. In such systems the second and higher neighbour distances are generally less well defined and the PDF peaks are broader. However, in crystals, because of the long-range order of the structure, all neighbours at all lengths are well defined and give rise to sharp PDF peaks (Levashov *et al.*, 2005). The position of these peaks directly gives the separations of pairs of atoms in the structure. If data are measured with high enough $Q_{\max}$, finding the position of a peak maximum will give the distance separating a pair of atoms in the material. If the structure is known well enough, the particular atoms contributing to that peak can also be deduced.

If a well defined PDF peak can be observed, we can determine the coordination number of the origin atom by integrating the intensity under that peak in the radial distribution function according to equation (5.7.20). For the case of Ni, when we construct our PDF we will therefore place 12 units of intensity at position r = 2.49 Å for each nickel atom placed at the origin. Since there are four Ni atoms in the unit cell this will be 48 units of intensity at this position (the weighting factor, $f_m f_n / \langle f \rangle^2$, is unity since there is only one kind of scatterer so $\langle f \rangle^2 = f^2$) and divide by N = 4 since we put four atoms, respectively, at the origin. Thus, integrating the first peak will yield 12, which is the coordination number of Ni. The same information can be obtained from multi-element samples if the chemical origin of the PDF peak and therefore the weighting factors are known. If, as is often the case, PDF peaks from different origins overlap this process may become complicated. As we discuss later, full-scale structural modelling largely overcomes the problem of PDF peak overlap, at least in crystalline materials.

As discussed, the PDF peaks are broadened from delta functions to Gaussian, or nearly Gaussian, shaped peaks. In cases where an atomic probability distribution function is non-Gaussian, for example if the atomic potential is multi-welled and atoms in the solid occupy each well in some disordered fashion, the PDF will reflect this and in principle this information can also be extracted from the PDF by an analysis of the PDF peak shape.

To summarize, there are three independent pieces of information which are contained in a PDF peak: its position gives the average separation of the pair of atoms in question; its integrated intensity yields the coordination number of that pair of atoms; and the width and shape of the peak gives the underlying atomic probability distribution.

5.7.5.4. *Modelling approaches*

In practice, the most information, and the most quantitatively reliable information, is obtained by fitting structural models to the data. The PDF is calculated from the model according to the method described in Section 5.7.5.1. Once the model PDF has been calculated it can be compared to a PDF derived from data to assess how good the structural model is. At this point it is typical to quantify the 'goodness-of-fit' with a suitably defined residuals function, often labelled as R_w. It may be defined in different ways, but a common definition is

$$R_w = \left(\frac{\sum_{i=1}^{n} w(r_i)[G_{\rm obs}(r_i) - G_{\rm calc}(r_i)]^2}{\sum_{i=1}^{n} w(r_i) G_{\rm obs}^2} \right)^{1/2}, \qquad (5.7.65)$$

where the w's are weights (often the inverse square of the data standard deviations) and $G_{\rm calc}$ and $G_{\rm obs}$ are the calculated and measured $G(r)$ functions, respectively.

Models may be compared with each other by comparing their goodness of fit. The model with the lower goodness-of-fit parameter is the better model if the difference is significant. The difference between models is significant if the difference in the goodness of fit exceeds the uncertainty in this parameter coming from the random errors in the data (Billinge *et al.*, 1991). The process of improving models may then be automated using a regression technique where model parameters are allowed to vary, subject to certain user-defined constraints, and these variations continue until a minimum is found for the goodness-of-fit parameter. An example of a converged fit is shown in Fig. 5.7.12.

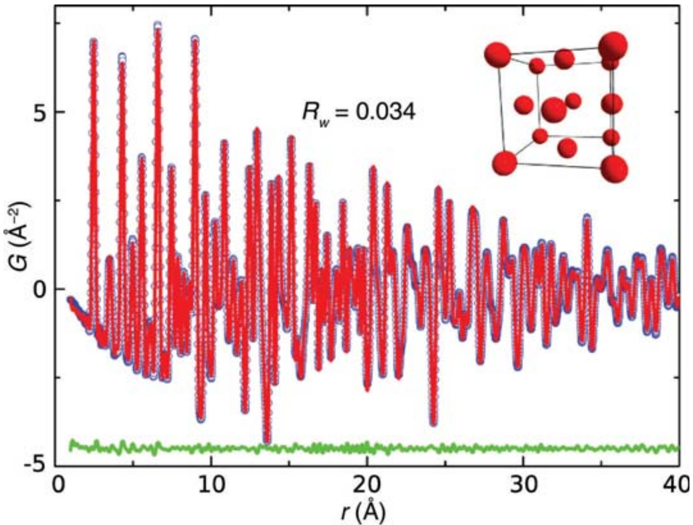

Figure 5.7.12
PDF fit of crystalline nickel. Blue circles and red curves correspond to experimental and calculated PDFs, respectively, with the green difference curve offset below. The inset shows the crystal-structure model.

Roughly speaking there are two different philosophies used for calculating models ('big-box' and 'small-box' modelling) and there are a wide range of different approaches used for the minimization procedure. The small-box approach for calculating the model is to specify the smallest possible unit cell that explains the structure and to calculate the PDF from this unit cell. Distributions in the atomic distances are accounted for by convoluting the resulting calculated PDF with Gaussian functions. The basic unit cell is periodically repeated in space as far as is necessary to calculate the PDF to the required $r_{\rm max}$.

The 'big-box' approach is to model the sample as a large box of atoms which is much larger than the range over which the PDF is to be calculated. In this approach the atomic distributions due to thermal motion are either explicitly included in the distribution of atom positions in the box or, if the box does not contain enough atoms to give smooth distributions, the convolution approach can be used, or the two approaches can be combined. As time goes on, the distinction between these modelling approaches is becoming somewhat blurred as the number of parameters in small-box models increases. It should be pointed out that once a structural model has been defined, both the scattering in Q space and the PDF can easily be calculated. Since the PDF is simply the Fourier transform of the total-scattering structure factor, the model could be fitted to the data in real or reciprocal space. Since the data are the same, each approach should yield the same information, but there is often debate about which approach is superior. Even though it is true that $S(Q)$ and the PDF contain the same information, there are some pertinent differences between the two representations and it turns out that, from a practical point of view, the two representations lend themselves to being modelled in different ways. Depending on the question being asked, the answer is often more accurately determined in one representation or the other.

5.7.5.4.1. *Small-box modelling*

The Rietveld full-profile fitting method (Rietveld, 1969) for extracting structural information from crystalline powder diffraction patterns revolutionized the use of powder diffraction for structure studies (Young, 1993), as discussed in detail elsewhere in this volume.

This approach has been applied in exact analogy but to the PDF (Billinge, 1998) in the programs *PDFFIT* (Proffen & Billinge, 1999) and more recently *PDFgui* (Farrow *et al.*, 2007). We highlight here the similarities and differences of this PDF fitting with conventional Rietveld fitting. The main similarity is that the model is defined in a small unit cell with atom positions specified in terms of fractional coordinates. The refined structural parameters are the same as those obtained from the Rietveld method (with a few additional structural parameters needed in the PDF). The main difference from the conventional Rietveld method is that the local structure is being fitted, which contains information about short-range atomic correlations. There is additional information in the data, which is not present in the average structure, about disordered and short-range ordered atomic displacements. To successfully model these displacements it is often necessary to use a unit cell that is larger than the crystallographic one. It is also a common strategy to introduce disorder in an average sense without increasing the unit cell. For example, in the case where an atom is sitting in one of two displaced minima in the atomic potential, its probability of being in either well is random, can be modelled as a split atomic position with 50% occupancy in each well. This is not a perfect approximation of the real situation but it is a very good aproximation, and is very useful as a first-order attempt at modelling the data.

This 'real-space Rietveld' approach is proving to be very useful and an important analysis approach for PDFs from crystalline and nanocrystalline materials. First, its similarity with the Rietveld method means that a traditional Rietveld-derived structure can be rapidly compared, quantitatively, with the PDF. This is an important first step in determining whether there is significant evidence for local distortions beyond the average structure. The Rietveld model is refined to the PDF without relaxing any of the symmetry constraints of the crystallographic model. The resulting fit can be assessed to look for significant deficiencies. In addition, the refined parameters can be compared directly with the results from the Rietveld fitting to make sure they are consistent. If evidence exists to suggest that local structural distortions beyond the average structure are present, these can then be incorporated in the PDF model. The second strength of the real-space Rietveld approach is the simplicity of the structural models, making it quick and straightforward to construct the structural models and making physical inferences from the models similarly quick and straightforward.

One piece of additional information in the PDF that cannot be determined from a conventional Rietveld refinement is information about motional correlations. Directly bonded near-neighbour atoms tend to move in phase with each other and their motion is positively correlated (Jeong *et al.*, 1999, 2003). This is illustrated in Fig. 5.7.13.

Because the PDF is a *pair* correlation function, if the motion of atoms is perfectly correlated (*i.e.*, they move together as if connected by a rigid rod) the PDF peak between those two atoms will be a delta function, even though the atoms are moving (Fig. 5.7.13*a*). On the other hand, if the motions of neighbours are completely uncorrelated, as if they were contained in separate boxes with solid walls (Fig. 5.7.13*b*), the width of the PDF peak between each pair would be broad and correspond to the Gaussian widths of each atomic probability distribution function added in quadrature. In general the situation is somewhere between these limits, crossing over to uncorrelated behaviour for widely separated neighbours (Fig. 5.7.13*c*). If the bond is very stiff, the relative motion of these neighbours with respect to each other can be quite small. For example, in covalent semiconductors the nearest-neighbour motion may be >80% correlated (Jeong *et al.*, 1999). The motion of far neighbours is uncorrelated: the motion of an atom at position *A* has no effect on the motion of atom at position *B* that is far from *A*. The thermal factor measured in a conventional crystallographic refinement is the uncorrelated one. This often reflects the softest bonds in the material. For example, in the semiconductor alloys it reflects the weak bond-bending forces. The stiff bond-stretching force can be measured from the correlated motion of the near neighbours, which is obtained directly from the width of near-neighbour peaks in the PDF.

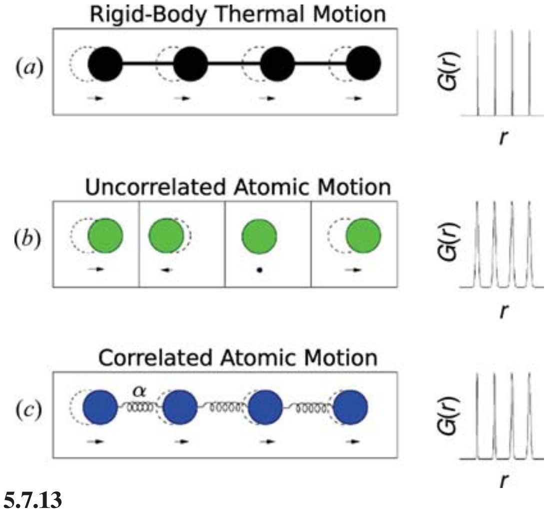

Figure 5.7.13
A schematic of three different motional correlations of atoms and their corresponding PDFs. (*a*) Completely correlated thermal motion, (*b*) uncorrelated thermal motion and (*c*) partially correlated thermal motion. Adapted from Jeong *et al.* (2003).

When local atomic displacements away from the average structure exist, and therefore significant diffuse scattering intensity is present in the scattering, a conventional Rietveld refinement becomes inadequate in principle. At this point a model is required that can fit both Bragg and diffuse intensities and that includes short-range ordered structures that are different from the average structure. This is readily done in real space where there is a natural separation in *r*, where it is now common to fit different models to explain the low-*r* region and the high-*r* region.

The approach was developed to study local structure in crystalline materials, but has found a natural extension to nanoparticles, clusters and nanoporous systems (Billinge & Kanatzidis, 2004; Masadeh *et al.*, 2007; Billinge, 2008).

5.7.5.4.2. *Big-box modelling*

In big-box modelling a model is created with often many tens of thousands of atoms in a box to simulate the solid. The PDF is then calculated from this model and compared to the measured PDF (of course the comparison can also be made in reciprocal space). Because of ergodicity, the temporal and ensemble averages of the ensemble of atoms in the real sample will give the same PDF. This may be used in the modelling since if the box contains enough atoms, the average PDF of those atoms can be used to simulate both static and dynamic disorder. Large boxes and/or multiple distinct configurations of the model are needed to get sufficient statistics on the calculated PDF to give a good agreement to the measured one.

Direct simulations of solids may also be done this way. For example, given an interatomic pair potential that gives the energy of pairs of atoms as a function of their separation, it is possible to put a large number of atoms in a box and to calculate the energy of the configuration. It is useful to then have a method to find the configuration that yields the minimum energy. This is a classic global-optimization problem and there are various algorithms for minimizing the energy. One of the most widely used is the Metropolis simulated annealing algorithm (Metropolis & Ulam, 1949). In the Metropolis algorithm, atom positions are allowed to vary in some random way. After each change the energy of the system is calculated using the specified potential-energy function. If a change reduces the energy of the system it is accepted. If it raises the energy of the system then it can be accepted or rejected. This decision is made randomly according to an underlying probability. It is this gambling aspect of the technique that gave it its name: the Monte Carlo algorithm. In simulated annealing the underlying probability governing whether a move is accepted is given by

$$P = \exp(-\Delta E/kT), \tag{5.7.66}$$

where ΔE is the change in energy, k is the Boltzmann constant and T is the 'temperature' of the system, which is initially set by the experimenter. When T is higher, more 'bad' moves are accepted and more of the energy landscape is probed by the simulation (it is easier to get out of local minima). The temperature can then be systematically lowered to guide the simulation into the global energy minimum. This is a widely used and powerful method in statistical physics and the computational technology is well developed (Binder & Heerman, 1992).

Clearly, Monte Carlo simulated annealing is a powerful approach to minimization of any parameterized function and is particularly applicable if there are a large number of parameters and a complicated parameter space. From this perspective, it lends itself to being applied to solving complicated structural problems, where the function to be minimized is not an energy but a residuals function. In this case there is no obvious reason why the underlying probability should be a Boltzmann distribution as in standard simulated annealing. However, in the absence of rigorous arguments justifying the adoption of another form for the probability distribution, and the extensive understanding that exists of the behaviour of simulated annealing with the Boltzmann distribution, this was the natural place to start. This approach is termed Reverse Monte Carlo (or RMC) following the pioneering work of McGreevy & Pusztai (1988), although there are some examples of similar approaches extending back to the 1960s (Kaplow *et al.*, 1968; Renninger *et al.*, 1974; Dmowski *et al.*, 1988).

The use of simulated annealing to minimize a residual function constitutes solving the 'inverse problem' of diffraction. The direct problem is: given a 3D arrangement of atoms, what is the diffraction pattern (or in this case the PDF)? The inverse problem is: given a PDF, what is the 3D structure that gave rise to it? The PDF data are the input to the inverse problem; the structural model is then fitted to the data by adjusting atom positions to minimize the residuals function. The problem is that, in general, the model is under-constrained, in which case there is not enough information in the data to yield a unique solution. This is the case of an ill-posed inverse problem. The great difficulty in all modelling, but big-box modelling in particular, is to know whether the resulting inverse problem is well posed or not. Despite this difficulty, it is still of value to model in this way. Any approach that provides physical insight and helps gain valuable understanding about the data is valid, as long as the conclusions drawn from the study are not overreached. Particular care should be taken to avoid overreach in more disordered systems, where the structural information is limited and there can be an enormous degeneracy in possible structural solutions consistent with the same data set. If one does not constrain the structural model in physically reasonable ways the structure solution is quite likely to be wrong and often unphysical (Keen, 1998).

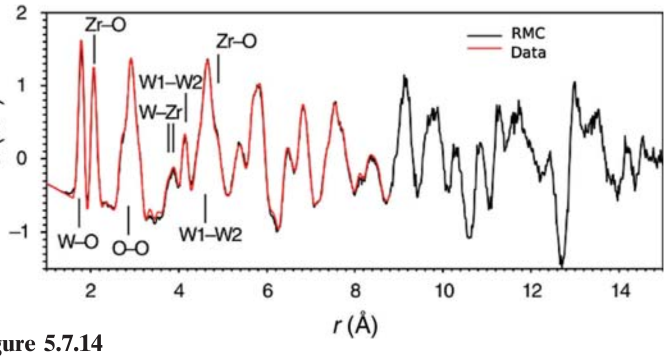

Figure 5.7.14
An example of an RMC refinement to the neutron total-scattering data of ZrW_2O_8. Reprinted with permission from Tucker *et al.* (2005). Copyright (2005) by the American Physical Society.

When faced with data from a crystalline material, a great deal is known about the structure from a conventional crystallographic analysis. It is clearly inefficient, and most probably disastrous, to specify the starting model by placing atoms randomly in the box and hoping that the correct crystal structure is found by random mutations of the model. In this case, a more conventional refinement is preferred where a well defined starting model is specified and this is allowed to distort randomly to fit the data. When a Monte Carlo algorithm is used for the regression the term 'RMC refinement' has been coined (Keen, 1998), distinguishing the approach from RMC modelling as described in the previous paragraph. An example of an RMC refinement is shown in Fig. 5.7.14.

As RMC modelling becomes more constrained (Tucker *et al.*, 2007) the distinction between small- and large-box modelling becomes somewhat cloudy; however, it is useful to distinguish the two approaches since in many people's eyes RMC equates to unconstrained RMC modelling with all its shortcomings.

For modelling local structure in crystalline systems, a number of powerful RMC refinement codes are emerging, mostly around the *RMCprofile* program (Tucker *et al.*, 2007), including a graphical user interface (http://www.rmcprofile.org). *RMCprofile* is good for incorporating additional constraints into the modelling; for example, it includes the Bragg profile in the fit for greatly improved reliability. A number of other RMC modelling and refinement codes are also freely available. Used mostly for disordered materials, *RMC++* is still under active development (http://www.szfki.hu/~nphys/rmc++/opening.html) (Evrard & Pusztai, 2005; Gereben *et al.*, 2007). As well as its special features for modelling nanoparticles using evolutionary algorithms, the *DISCUS* program (http://discus.sourceforge.net) also has an implementation of RMC (Proffen & Neder, 1997; Neder & Proffen, 2008). Other efforts include incorporating EXAFS data (Krayzman *et al.*, 2008, 2009) and prior chemical knowledge in the form of bond-valence sums (Norberg *et al.*, 2009) into big-box modelling schemes.

Empirical potential structure refinement (EPSR) (Soper, 1996, 2001, 2007) may be used for extracting structural information about solvation states of ionic and molecular complexes in solution. In general, multiple neutron liquid structure factors and PDFs with different kinds of deuteration are used in the

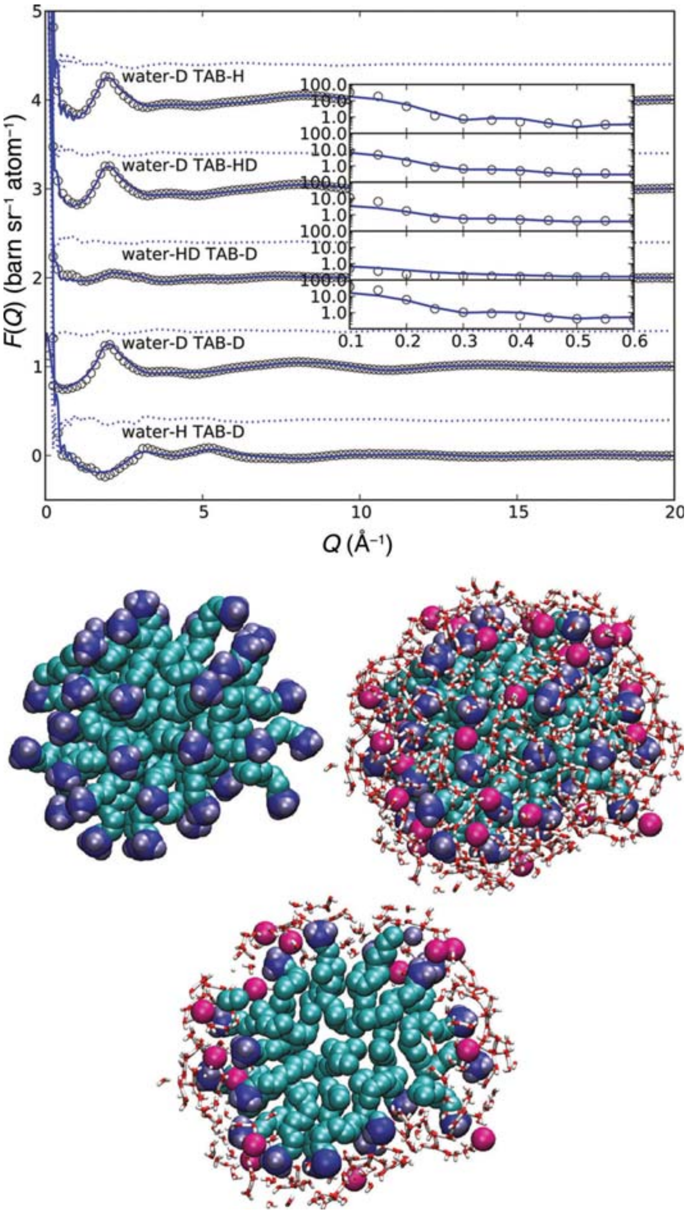

Figure 5.7.15

Total-scattering structure functions, with low-angle scattering (inset) from surfactant micelles of CTAB with different substitutions of hydrogen/deuterium. Representative structures are shown below: (top left) surfactant molecules, (top right) micelle surrounded by bromide counterions and water, and (bottom) a cross section with a width of 12 Å. fitting. An excellent strategy for studying hydrogenated liquids and hydrogenated solute species is to preferentially deuterate different parts of the system and collect complementary data sets. The problem of collecting data from liquid systems containing hydrogen is also large, but largely solved, with the specially designed SANDALS and NIMROD diffractometers at ISIS. The modelling uses a big-box approach, but only a small number of parameters are refined: the parameters that define an interatomic potential between the atoms. A scheme is then used to refine the values of the potential parameters to give a good fit to all the data. This approach has proved to be very powerful in the study of complex liquids (Soper, 1996; Landron *et al.*, 2001; Hargreaves *et al.*, 2011). An example of EPSR fits to multiple different PDFs from differently deuterated samples of the surfactant CTAB, and the resulting structural models, are shown in Fig. 5.7.15.

Often something is known about the network connectivity of a structure and constraints can be introduced that maintain the network. Two such examples are geometric modelling (Wells *et al.*, 2002, 2004; Sartbaeva *et al.*, 2007) and a similarity constraint that ensures that every atom has the same local environment as every other atom (Cliffe *et al.*, 2010). Efforts are underway to use the advantages of modern object-oriented programming methods to modularize the process of building complexed models, and a complex modelling framework named *Diffpy-CMI* is under construction (http://diffpy.org). The modularity allows diverse fits to be built on the fly with great flexibility. The software has been released and has been a key component in a number of recent scientific studies where the modularity allowed modelling extension to be rapidly implemented (Jensen *et al.*, 2012; Tyrsted *et al.*, 2012; Farrow *et al.*, 2013; Yang *et al.*, 2013).

5.7.5.4.3. *Ab initio nanostructure solution from PDF data*

Outside the world of glasses and liquids, virtually all of the PDF modelling that has been done to date is refinement of a known (or guessed) starting model. However, crystal structures may be solved from powder diffraction data (David *et al.*, 2002). It was recently demonstrated that in some cases it is also possible to solve nanoparticle (Juhás *et al.*, 2006, 2008; Cliffe *et al.*, 2010) and crystal (Juhás *et al.*, 2010) structures directly from the PDF. The first structure solution from PDF data was achieved by developing a new regression algorithm that was based on a cluster-building approach, starting from small clusters and then building them up to form larger clusters. The algorithm competed clusters of the same size against each other to see which agreed best with the data. Well performing clusters could get 'promoted' to a higher division by adding one or more atoms. This league-table aspect gave rise to the name *LIGA* after the Spanish soccer leagues. The basic philosophy behind the new *LIGA* algorithm was that the PDF function is an *r*-dependent function. Any smaller sub-cluster of the total cluster must give PDF peaks that are consistent with the peaks in the lower-*r* region of the PDF. On the other hand, a sub-cluster that gives peaks in the wrong place must be wrong. Using the information contained in the PDF to guide the construction of trial models enormously reduces the search space for the global optimization, although the search space remains large. There are still many clusters and many incorrect sub-clusters that nonetheless are consistent with the low-*r* part of the PDF, so a backtracking method is required so that when promising but wrong clusters are built out, they can be taken apart again and rebuilt differently. Information in the PDF is again used when selecting 'bad' atoms to remove from the cluster, since atoms on the cluster may be scored based on how many incorrect distances they contribute to the PDF. The worst performing atoms are removed with higher probability. The algorithm is described in detail in Juhás *et al.* (2006), with all the implementational details described in Juhás *et al.* (2008). For structures with a high degree of self-similarity, such as high-symmetry C_{60}, there is a good match between the number of distinct peaks in the PDF and the number of atoms that need to be placed, and the algorithm worked very efficiently. For example, it found the solution to C_{60} from ideal data in less than a second, and from noisy data in a few minutes, on a laptop computer (Juhás *et al.*, 2006, 2008). The process for obtaining the structure solution is illustrated in Fig. 5.7.16.

More recently, the addition of one more constraint to the C_{60} problem, a similarity constraint that ensured that every atom had the same environment, allowed the structure to be solved *ab*

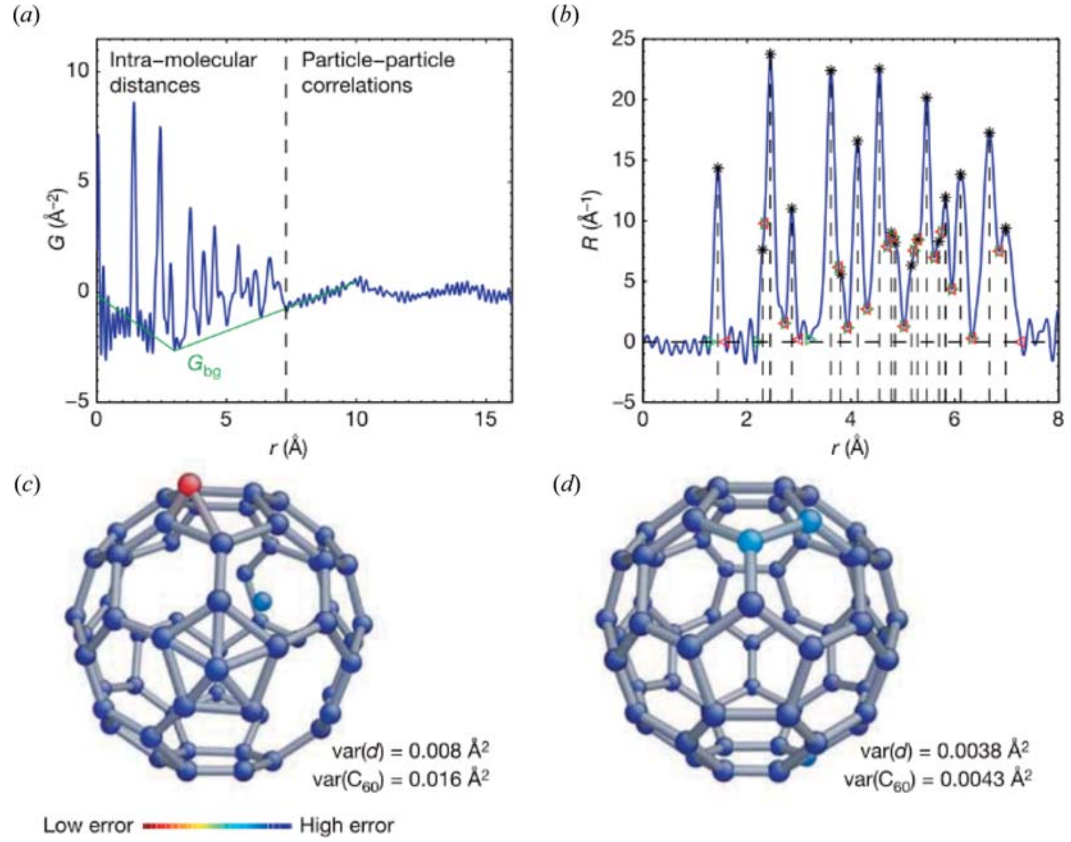

Figure 5.7.16
Structure solution of C_{60} from neutron PDF data using the *LIGA* algorithm (Juhás *et al.*, 2006). (*a*) The measured PDF, including intra- and intermolecular correlation functions. (*b*) The RDF of just the intramolecular part after removal of the intermolecular part. (*c*) Structural solution containing errors due to too strict adhherence to noisy data. Blue atoms contribute small errors and red ones high errors to the agreement. (*d*) The correct solution is obtained when the model is allowed to deviate from the strict intensities of the data, making it less susceptible to noise and resulting in the correct structure solution. Adapted from Juhás *et al.* (2006).

initio using simulated annealing (Cliffe *et al.*, 2010). This is an easier problem for the algorithm to solve than the original problem, where the structure was recreated from the data alone. The added constraint greatly reduces the search space of the solution space, showing the power of judicious addition of constraints in modelling. In fact, the symmetry of C_{60} is very high, and if the full symmetry of the molecule is known only two parameters need to be specified in order to solve its structure (David *et al.*, 1993). It is a thus a great example of the use of constraints in helping to solve nanostructure problems and gives hope that complex modelling will be successful in practice as well as just sensible in theory.

SJLB would like to acknowledge help in preparing the figures from Maxwell Terban, Chenyang Shi, Benjamin Frandsen and Kirsten Jensen, and Maxwell Terban for editorial help. 5.8. Scattering methods for disordered heterogeneous materials

A. J. Allen

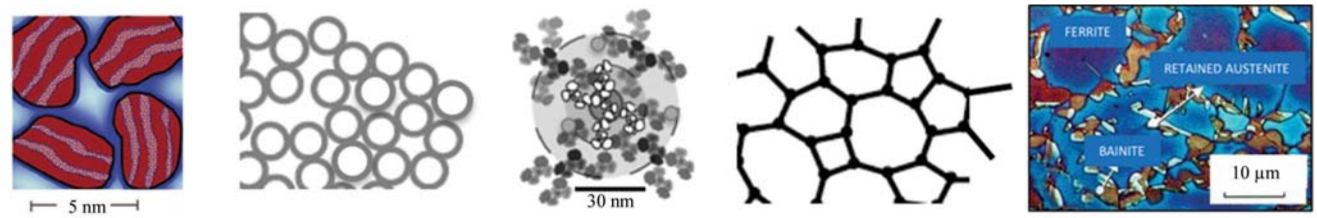
5.8.1. Introduction and overview

5.8.1.1. *Amorphous and non-crystalline materials*

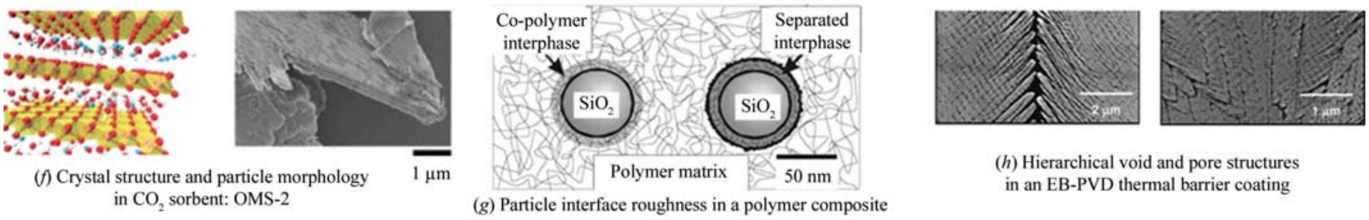
While powder diffraction and single-crystal diffraction have long comprised the standard means for determining the structure, phase and even the composition of solid materials, standard powder or single-crystal diffraction methods cannot be applied if no (or little) crystalline structure is present. The most obvious examples of amorphous and non-crystalline solid materials are glasses, polymers, various types of gel and sometimes thin films. A uniform amorphous material without structure at any length scale would not be very tractable to diffraction-based measurements of almost any kind. Fortunately, only a few (if any) materials amorphous over all length scales exist in nature. Most so-called amorphous materials contain some short-range order that can be elucidated, at least to some extent, by wide-angle liquid- or total-scattering methods increasingly available at synchrotron X-ray or neutron scattering facilities. Such methods are also applicable to poorly crystalline solids where defects and other heterogeneities disrupt any long-range order, and also to nanocrystalline materials where the crystal structure order is short range by definition (Bates *et al.*, 2006). Since wide-angle scattering (WAS) methods in general, and nanocrystalline materials in particular, are covered elsewhere in this volume (see Chapters 5.6 and 5.7), they will be discussed fairly briefly in this chapter. Here we will focus more on the disorder and heterogeneity at the microstructural level (from ∼10 Å to several μm), which pervades all material systems (including thin films) that are not uniform in structure and composition across all length scales.

5.8.1.2. *Disordered and heterogeneous (and multi-component) materials*

Fig. 5.8.1 presents examples of measurements possible for disordered and heterogeneous materials, together with the scale ranges applicable to the techniques discussed.



(*a*) C-S-H gel globules with internal structure (*b*) Colloidal dispersion (many possible length scales) (*c*) Fractal aggregate of C-S-H gel globules (*d*) Continuous random network (many possible length scales) (*e*) Phase transformations, defects and precipitates in an advanced steel



(*f*) Crystal structure and particle morphology in CO_2 sorbent: OMS-2 (*g*) Particle interface roughness in a polymer composite (*h*) Hierarchical void and pore structures in an EB-PVD thermal barrier coating

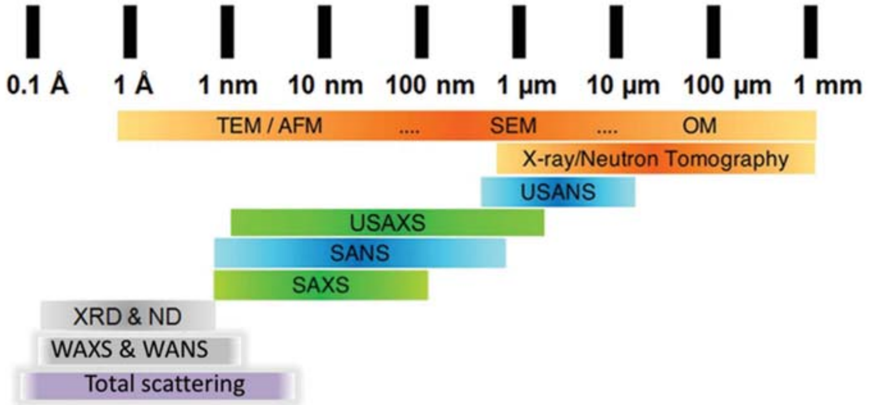


Figure 5.8.1

Examples of scattering methods applied to disordered, heterogeneous materials, together with the scale ranges of interest and the applicable scattering-based methods. Material examples: (*a*) calcium-silicate hydrate (C-S-H) gel globules in hydrating cement (Allen *et al.*, 2007); (*b*) colloidal particle dispersion (Bates *et al.*, 2006); (*c*) fractal aggregate of C-S-H gel globules (Jennings, 2000); (*d*) continuous random network [as (*b*)]; (*e*) complex microstructure of an advanced steel; (*f*) crystal layer structure and associated lamellar morphology of CO_2 solid sorbent, OMS-2 (Espinal *et al.*, 2012); (*g*) interphase-controlled interface surface roughness between particles and matrix in a polymer composite (Wilson *et al.*, 2007); and (*h*) void/pore structures in an electron-beam physical vapour-deposited (EB-PVD) thermal barrier coating (Renteria *et al.*, 2007). Techniques: TEM and SEM = transmission and scanning electron microscopy, AFM = atomic force microscopy, OM = optical microscopy (microscopies and imaging included for comparison); SAXS and SANS, USAXS and USANS = small-angle and ultra-small-angle X-ray and neutron scattering; XRD and ND = X-ray and neutron diffraction (structure determination); WAXS and WANS = wide-angle X-ray and neutron scattering (phase analysis, diffuse-scattering effects); and total scattering (atomic pair distribution function analysis).

Table 5.8.1
Information on disordered or heterogeneous material systems using scattering methods

Abbreviations: GI-SAXS = grazing-incidence SAXS, NS-SANS = near-surface SANS, XRR = X-ray reflectivity, NR = neutron reflectivity.

Q-range, obtainable information (examples or applications)	SAXS, SANS	USAXS, USANS	GI-SAXS, NS-SANS	XRR, NR	WAXS, WANS	Total scattering
Minimum Q (Å^{-1})	10^{-3}	$< 10^{-4}$	10^{-3}	$\sim 10^{-1}$	1	~1
Maximum Q (Å^{-1})	1	1 or 10^{-3}	1	> 1	~5	> 40
Lattice spacings, crystal phases (precipitates/minority phases in alloys, CO_2 solid sorbents)					×	×
Mean particle or pore size, shape (colloids, porous rocks)	×	×	×	×		
Size distribution (precipitate nucleation, growth and coarsening)	×	×	×			
Pore or particle volume fraction (solution-mediated particle formation, cement hydration)	×	×				
Pore, particle or interface surface area and roughness (coating de-lamination, composite particle/matrix bonding)	×	×	×	×		
Composition, density of solid phases or layers (deposited dielectric films, clays, catalysts)	×	×	×	×	×	
Interparticle interactions (concentrated suspensions, gels)	×	×	×	×		
Particle or pore pair distribution function (concentrated suspensions, gels, fractal aggregates, cements)	×	×	×	×		
Local structure and atomic pair distribution function (quantum dots, nanoparticle internal crystal structures)					×	×

Many material systems exhibit heterogeneity and disorder, regardless of whether they contain components with crystal structure or not. As reviewed by several authors (*e.g.* Fratzl, 2003; Allen, 2005), obvious examples include nanoparticle (or small-particle) dispersions in liquid, cements and concretes, clays and minerals (including oil shales), porous solids of all kinds, thermal barrier coatings, nanocomposites, precipitates in metals and alloys, and even biological structures. Some more specific examples are given in Fig. 5.8.1 that demonstrate how the heterogeneous nature of a material may comprise a size distribution of discrete pores or particles, may comprise a network structure (as is frequently the case with polymers), or it may be hierarchical in nature, possibly exhibiting a fractal structure of some kind. The heterogeneity is usually disordered but, if not, coherent-diffraction hallmarks will be apparent that can be treated by an extension of crystal-diffraction principles to the microstructural ordering at coarser length scales. For a general disordered material system, small-angle scattering (SAS) methods can be applied (Kostorz, 1979), and these comprise the techniques most discussed in this chapter.

5.8.1.3. *Small-angle and wide-angle scattering tools*

As with all diffraction-based scattering techniques, the scattering intensity, as a function of the scattering-vector magnitude Q [where $Q = 4\pi \sin\theta/\lambda$, λ is the wavelength of the radiation used and 2θ is the scattering angle], is related to the Fourier transform of the structure or microstructure of interest. Whereas for powder or single-crystal diffraction the scattering forms the diffraction pattern associated with the particular crystal structure being investigated, for SAS/WAS the scattering can also be associated with the Fourier transform of the atomic density distribution within the sample. In the case of a disordered material system this relates to the mean microstructure arrangement averaged over the sampling measurement volume and measurement time. Small-angle X-ray and neutron scattering (SAXS and SANS) are becoming increasingly important methods for measuring the statistically representative, volume-weighted microstructures of disordered and heterogeneous material systems (Guinier & Fournet, 1955; Glatter & Kratky, 1982). Where possible, they should be used in conjunction with wide-angle X-ray or neutron scattering (WAXS and WANS) to provide quantitative phase information for the components of the heterogeneous system. Furthermore, total-scattering studies over an extended Q range, such as are possible at synchrotron X-ray beamlines or at pulsed neutron source facilities, can provide additional information on the local structure factor that defines any short-range order that may be present, and may also be used to determine, for example, the atomic pair distribution function inside diffracting nanocrystalline grains (Proffen *et al.*, 2003; Billinge & Levin, 2007; Keen & Goodwin, 2015). Total-scattering methods also supply information on thermal diffuse scattering from lattice vibrations. Thus, wide-angle and total-scattering methods should be used in conjunction with SAXS and SANS, and are discussed below for relevant situations, but our primary focus is on SAXS and SANS.

5.8.1.4. *Tabulated summary of quantitative information obtainable*

Table 5.8.1 summarizes the information obtainable from the techniques discussed in this chapter. While specific issues regarding the limitations and experimental uncertainties of the various techniques are discussed in the sections that follow, some general points can be made here. Most, but not all, scattering- and diffraction-based methods incorporate detectors that count events (*e.g.* scattered X-ray photons or neutrons) through associated electronic pulses of some kind. Thus, most statistical uncertainties in the measured intensities can be readily calculated and propagated through the data reduction (circular or sector-averaging of position-sensitive detector counts, blank-run-data subtraction, calibration and normalization, *etc.*). However, much of the data analysis and interpretation involves geometrical desmearing steps, separation of different scattering or diffraction phenomena, and Fourier transformations from the measured data in Q-space to structural and microstructural information in real space. Thus, it is critical that uncertainties and variation in the measured intensities remain sufficiently small so as not to introduce artifacts into the extracted structural information. Other sources of uncertainty in the structures and microstructures determined arise from finite resolution in Q, truncation effects due to the finite Q range considered, and the degree to which any one interpretative or model scheme is appropriate. These issues can play a particularly important role where different techniques are combined together for partially disordered material systems.

5.8.1.5. *Different notations*

The notation used in this chapter corresponds to that generally used in neutron scattering, although it is also increasingly used in X-ray scattering measurements carried out at X-ray synchrotron facilities. However, a different notation has also been associated with X-ray crystallography, especially small-angle X-ray scattering. See for example, Chapter 2.6 of *International Tables for Crystallography* Volume C (Glatter & May, 2006) and other texts (Guinier & Fournet, 1955; Glatter & Kratky, 1982). The principal difference in these earlier texts of relevance here is that h is used in place of Q, and $\mathbf{h}$ in place of $\mathbf{Q}$ when the direction of the scattering vector must be considered. (Note that q and $\mathbf{q}$ are also common notations corresponding to Q and $\mathbf{Q}$.) As is well covered in these earlier texts and *International Tables*, $\mathbf{h} = (2\pi/\lambda)(\mathbf{s} - \mathbf{s}_O)$, where $\mathbf{s}$ and $\mathbf{s}_O$ are unit vectors in the scattered and incident directions, respectively. Nowadays it is more common to see $\mathbf{Q}$ defined by $\mathbf{Q} = \mathbf{k} - \mathbf{k}_O$ where $\mathbf{k}$ and $\mathbf{k}_O$ are the scattered and incident wave vectors (of magnitude $2\pi/\lambda$).

5.8.2. Recommended measurement tools

All of the techniques discussed here utilize either X-rays or neutrons. We acknowledge the importance of light-scattering methods for the measurement of dilute, transparent, disordered systems at the micrometre scale. However, these techniques have limited applicability here, with the possible exception of dilute particulate suspensions, and they are well described elsewhere. Also, we acknowledge that increasingly sophisticated electron-scattering methods have become available with high-resolution transmission electron microscope (HRTEM), scanning TEM (STEM) and cryogenic sample-based (cryoEM) instrumentation. However, HRTEM, STEM or cryoEM facilities do not yet provide the Q range, signal-to-noise and intensity dynamic range capabilities required for SAS and total-scattering analysis. Nor do they provide the intensity calibration needed to determine the absolute scattering probabilities and the associated volume fractions or concentrations of scattering features. For these reasons, we confine our discussion to X-ray- and neutron-based methods. For X-rays, where X-ray photons interact with the atomic electron distribution, the scattering intensity increases as the square of the atomic number (Z) density. For neutrons, where the main scattering contribution comes from neutron interactions with the atomic nuclei, there is generally greater *relative* sensitivity to low-Z materials, but this depends on the specific elements and isotopes present. In fact, the neutron isotope effect allows scattering contrast variation studies (see Section 5.8.3.1.10) to be made by adjusting the isotope mix, for example, between H_2O and D_2O. Since the neutron has a magnetic moment, there is also a magnetic interaction with any atomic magnetic moments present, which can be exploited in magnetic scattering experiments (see Section 5.8.3.1.11).

5.8.2.1. *Small-angle scattering using a position-sensitive detector*

Fig. 5.8.2 shows the basic measurement geometry used in SAS measurements using a two-dimensional (2D) position-sensitive detector (PSD), together with typical reduced SAS data *versus* Q. A well collimated incident beam impinges on the sample, in which a small component of the beam is scattered out of the forward direction by small scattering angles, 2θ. Generally, the incident beam is monochromatic, or at least sufficiently so to be associated with a fixed wavelength, λ, and the optimum instrument geometry occurs when the incident and scattered angular resolutions are the same. In the case of SAXS (Guinier & Fournet, 1955; Glatter & Kratky, 1982), although the X-ray beam can be tightly collimated by the crystal optics, as much as possible of the incident and scattered flight paths need to be in vacuum or a non-scattering gas because air scattering attenuates the X-ray intensity significantly. For laboratory-based SAXS facilities, the energy, E, and λ are determined by the X-ray source used – usually either Cu $K\alpha$ (E = 8.048 keV, λ = 1.5418 Å) or Mo $K\alpha$ (E = 17.479 keV, λ = 0.7107 Å) X-rays. At X-ray beamlines at synchrotrons, λ can be selected over a wide range, with a resolution usually determined by the band pass of the monochromator crystal optics. Generally, for SAXS, the illuminated sample area is $\sim$0.5 mm but can be <0.1 mm at a synchrotron. The sample thickness depends on the material and the X-ray energy, but typically ranges from 0.01 mm (high Z, low E) to 1 mm (low Z, high E).

In the case of SANS, the linear relationship between neutron wavelength and neutron time-of-flight is exploited (Grillo, 2008).

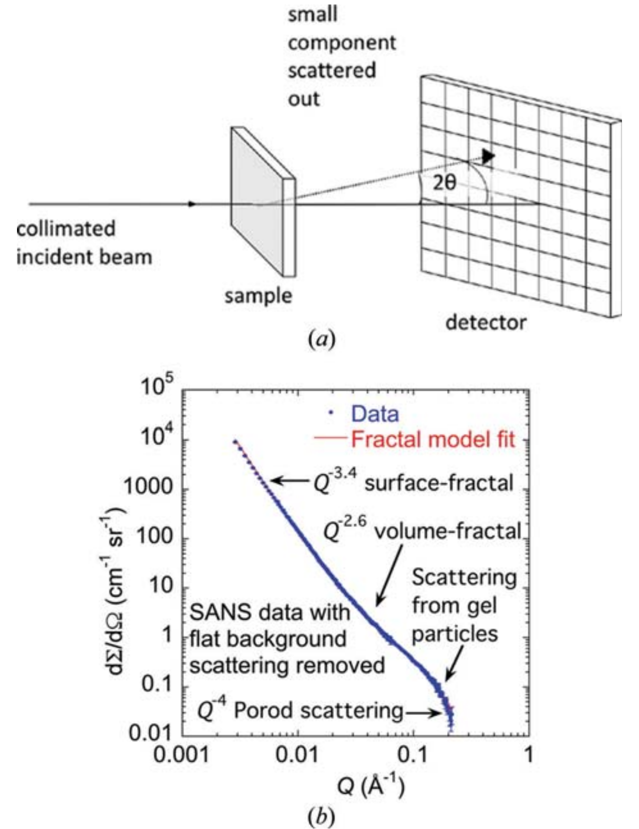

Figure 5.8.2
(*a*) Schematic of the basic measurement geometry for SAXS or SANS using a 2D PSD. The incident beam is monochromatic for SAXS and reactor-based SANS, and polychromatic for SANS at a pulsed source with energy/wavelength selection by time-of-flight. (*b*) Typical reduced and circularly-averaged SAS data with a fractal model fit (see Section 5.8.3.1.9). Vertical bars at each data point represent typical standard deviation uncertainties.

At a reactor-based neutron facility, λ is determined with typically 10 to 15% Δλ/λ resolution about a given value using a rotating helical velocity selector (only neutrons with a velocity, hence λ, along the incident direction within this band pass through the rotating helical path of the velocity selector). At a spallation neutron facility all neutrons are utilized in SANS measurements with λ for each time bin determined from the corresponding time of flight. In SANS, unlike SAXS, neutron waveguides are frequently used to collimate the neutrons as they travel from their effective source (fission or spallation) to an effective source slit at the exit of the last guide used. This aperture subtended at the sample position largely defines the incident-beam collimation, but the incident intensity decreases with the inverse square of the distance from this last guide to the sample position. The sample aperture (*i.e.* illuminated sample area) ranges from 5 to 20 mm with sample thicknesses ranging from 0.5 to 5 mm, depending on the material.

The 2D PSD measures the scattering intensity as a function both of the scattering angle, 2θ (hence Q), and the azimuthal angle about the incident-beam direction. Provided absolute intensity calibration is achieved (see Section 5.8.2.3) the objective in most SAXS or SANS measurements is to measure the differential scattering cross section, $\mathrm{d}\Sigma/\mathrm{d}\Omega$, as a function of Q. In this context, $\mathrm{d}\Sigma/\mathrm{d}\Omega$, for a given $\mathbf{Q}$, is defined as the scattering probability per unit incident flux and per unit sample volume of scattering into unit solid angle about the scattered beam direction associated with $\mathbf{Q}$. As in all diffraction processes, $\mathbf{Q}$ bisects the angle between the incident-beam direction and any given scattering direction (Fig. 5.8.2*a*). However, for small scattering angles, we note that this puts $\mathbf{Q}$ approximately in the sample plane. Thus, in the regular case of measurement transmission geometry, SAS primarily provides microstructural information within the sample plane, in a direction determined by the azimuthal direction of the scattering. When the microstructure within the sample is isotropic, or at least circularly symmetric about the incident-beam direction, data on the 2D PSD can be circularly averaged about the incident-beam direction and $\mathrm{d}\Sigma/\mathrm{d}\Omega$ can be expressed as a function of Q, rather than $\mathbf{Q}$. Indeed, the most common presentation of SAS data is in a three-column format of Q, $\mathrm{d}\Sigma/\mathrm{d}\Omega$ and the standard-deviation uncertainties in $\mathrm{d}\Sigma/\mathrm{d}\Omega$, together with the necessary metadata providing the measurement geometry, λ, Q resolution, sample thickness *etc.*, as well as details on the blank subtraction and the sample transmission. For SAXS or SANS with a 2D PSD, the standard-deviation uncertainties in $\mathrm{d}\Sigma/\mathrm{d}\Omega$ arise primarily from statistical uncertainties in the individual pixel detector counts. However, these must be propagated through the data-reduction software as the blank subtraction, intensity calibration and azimuthal or circular averaging steps are executed.

While data reduction to give $\mathrm{d}\Sigma/\mathrm{d}\Omega$ and data interpretation to model it are covered in more detail in later sections, we provide the basic theoretical basis for $\mathrm{d}\Sigma/\mathrm{d}\Omega$ here. At the fundamental level (Guinier & Fournet, 1955; Glatter & Kratky, 1982; Warren, 1990)

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega}(\mathbf{Q}) = \frac{1}{V_S}\left|\int\limits_{V_S} \rho(\mathbf{r})\exp(i\mathbf{Q}\cdot\mathbf{r})\,\mathrm{d}^3\mathbf{r}\right|^2, \qquad (5.8.1)$$

where $\rho(\mathbf{r})$ is the spatial distribution of the coherent X-ray or neutron scattering-length density over the sampling volume, V_S. While this equation could be applied in most diffraction-based analyses, in SAS it is more conveniently expressed in terms of the material microstructure being studied. For an isotropic microstructure consisting of scattering particles of particle number density n_P (*i.e.*, the volume fraction $\Phi_V = n_P V_P$), the squared integral in equation (5.8.1) can be converted to give a single integral in the SAS-applicable form of the Debye equation:

$$\begin{aligned}\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} &= n_P|\Delta\rho|^2 V_P \int\limits_0^\infty 4\pi r^2\gamma_0(r)\frac{\sin(Qr)}{Qr}\,\mathrm{d}r\\ &= n_P|\Delta\rho|^2 V_P^2 F_P^2(Q) S_P(Q),\end{aligned} \qquad (5.8.2a)$$

where $|\Delta\rho|^2$ is the scattering contrast factor between the particles and the surrounding medium, $\gamma_0(r)$ is the dimensionless atomic pair correlation function, V_P is the scattering particle volume, $F_P{}^2(Q)$ is the particle form factor, and $S_P(Q)$ is an interparticle structure factor containing information on the spatial relationship between the scattering particles. Here, we initially assume that $S_P(Q) = 1$ for a dilute population of uncorrelated particles, and we can write

$$F_P^2(Q) = \frac{1}{V_P}\int\limits_0^\infty 4\pi r^2\gamma_0(r)\frac{\sin(Qr)}{Qr}\,\mathrm{d}r$$

$$\text{where } \frac{1}{V_P}\int\limits_0^\infty 4\pi r^2\gamma_0(r)\,\mathrm{d}r = 1. \qquad (5.8.2b)$$

The particle form factor, $F_P{}^2(Q)$, can be expressed in terms of an assumed particle shape and/or real-space structure, *via* $\gamma_0(r)$, which decays to zero when r is greater than the maximum particle dimension, or it can be determined empirically from the data as a particle pair-distance distribution function (PDDF) (see Section 5.8.3).

Once again, we should mention a different convention frequently used in X-ray crystallography (Guinier & Fournet, 1955; Glatter & Kratky, 1982; Glatter & May, 2006). In this notation, a scattering intensity, $I(\mathbf{h})$ is used in place of $\mathrm{d}\Sigma(\mathbf{Q})/\mathrm{d}\Omega$ in equation (5.8.1) and the volume normalization is omitted. Similarly, $I(h)$ is used in place of $\mathrm{d}\Sigma/\mathrm{d}\Omega$ with the volume normalization omitted in equation (5.8.2*a*) *etc*. We use $\mathrm{d}\Sigma/\mathrm{d}\Omega$ as it is more readily related to what is actually measured in experiments, see Section 5.8.2.3.1.

Clearly, the measurement of $\mathrm{d}\Sigma/\mathrm{d}\Omega$ in a given Q regime requires sufficient Q resolution to gather the information potentially contained in the data. To cover a scale range of ∼10 Å to ∼0.1 mm, as is typical for conventional 2D SAXS or SANS, a corresponding Q range from ∼0.005 to ∼1 Å^{-1} is required, implying that several instrument configurations with different sample-to-detector distances (and corresponding incident-beam collimation) are required. In order to capture the microstructural information contained in the scattering profile, the Q resolution, defined by $\Delta Q/Q$, must be maintained for smaller Q values (larger scattering features). Also a correspondingly greater density of data points in Q is required if information is not to be lost. These requirements dictate tighter incident collimation and larger sample-to-detector distances for smaller Q values. However, the use of focusing optics at the more intense X-ray and neutron sources, coupled with new innovations in detector technology and the use of several 2D PSDs together, are opening up new possibilities in which SAXS or SANS data can be obtained across the whole Q range in one measurement, as discussed in Section 5.8.4.

Finally in this section, we discuss the requirements for 2D PSDs used in SAXS and SANS. Several technologies now exist for SAXS 2D PSDs: charge-coupled device (CCD) detectors, image plates and reverse-bias silicon-diode arrays are currently the most prominent types of X-ray 2D PSD (see Ponchut, 2006; Spieler, 2008). Several attributes need to be considered for SAXS applications: sensitive X-ray energy range, linear dynamic range in X-ray intensity, detector readout speed (this determines the cycling time, and hence time resolution of repeated measurements), spatial (pixel) resolution, signal-to-noise ratio, compactness and mass of overall detector system, and cost. All of these detector systems can be expensive, but they work well for X-ray energies up to ~12 keV. The detector efficiency generally declines for higher energies, but can be improved by increasing the thickness of the X-ray-sensitive materials. For SAXS, CCDs are compact, have reasonable linear dynamic range in intensity (14 to 16 bits), reasonable detector readout speed (a few seconds) and good spatial resolution (<100 µm pixel size), but can have significant dark-current noise that may limit application for weak scatterers. By comparison, image plates tend to be bulky and require more extensive cooling systems, can have better linear dynamic range in intensity (up to 18 bits) and have rather long readout times (~100 s) that severely limit time resolution, but have excellent spatial resolution (~10 µm pixel size) and low electronic backgrounds. SAXS 2D PSDs based on reverse-bias silicon-diode arrays or similar technologies currently present the best performance option (Eikenberry *et al.*, 2003).[1] They are light and compact, have excellent linear dynamic range in intensity (up to 20 bits), have very short detector readout speeds (a few milliseconds), acceptable spatial resolution for SAXS (<200 µm pixel size) and, as single-photon detectors, they exhibit zero dark current; but they are costly.

Development of 2D PSDs for SANS with good intensity dynamic range has progressed for several decades (Ibel, 1976; Glinka *et al.*, 1998) and continues, especially for new SANS instruments being installed at spallation neutron sources (Zhao *et al.*, 2010). Originally based on the absorption of neutrons in BF_3 gas, most SANS 2D PSDs now exploit the absorption of neutrons in ^{3}He gas (although the increasingly chronic shortage of ^{3}He is forcing renewed consideration of BF_3). In either case, neutron absorption results in a cascade of charged particles released in the gas close to the absorption site, and the resultant charge pulses registered on a 2D wire electrode array provide the intensity profile of the scattering intensity absorbed in the detector. The pixel resolution of SANS detectors is typically 5 to 10 mm. This is generally compatible with the larger scale of SANS instruments in general, but the detector pixel size subtended at the sample position must usually be taken into account in calculating the scattered-beam angular resolution. The dynamic intensity range of SANS 2D PSDs is more limited than for SAXS detectors (~14 bits). However, this limitation is partially mitigated for measurements at low Q where $d\Sigma/d\Omega$ is larger. This is because the larger SANS sample-to-detector distance, together with the correspondingly larger required collimation distance (between the source aperture at the exit of the last collimating neutron guide and the sample), very significantly reduce the measured scattering intensity at the detector. SANS 2D PSDs are very expensive, and there is a current need to develop new technologies, both for the new generation of SANS instruments at spallation neutron sources and to address a global shortage of ^{3}He.

5.8.2.2. *Ultra-small-angle scattering using crystal diffraction optics*

In conventional SAS with a 2D PSD the Q resolution is determined by the angular resolution associated with the incident and scattered beam geometries and also, especially for SANS, by the wavelength resolution. However, SAS measurements may also be made using Bonse–Hart crystal diffraction optics (Bonse & Hart, 1966; Long *et al.*, 1991). In this case, the Q resolution is defined by the band pass and Darwin width of the crystal optics used, and the resolution is decoupled from the source or sample apertures, and from the size of the point detector used. Because the minimum Q and Q resolution are significantly finer than possible with conventional SAS, lower Q values are accessible (corresponding to coarser feature sizes), and so the Bonse–Hart method is referred to as ultra-small-angle scattering (USAS, USAXS and USANS, corresponding to SAS, SAXS and SANS as described above).

Fig. 5.8.3(*a*) shows the configuration for a Bonse–Hart USAXS instrument. For both USAXS and USANS a pre-monochromated incident beam is passed through a pair of collimating crystals set to the Bragg condition for the appropriate wavelength. The X-rays or neutrons pass through the sample where small-angle scattering occurs, and then through a second pair of analysing crystals. The unscattered beam passes through both sets of crystal pairs (monoliths) when the analyser is also set to the appropriate Bragg condition. However, as the analyser is rotated away from this condition by a small angle 2θ, only X-rays or neutrons that have been scattered in the sample by the same angle satisfy the Bragg condition for the analyser monolith. Thus, a point detector placed after the analyser monolith can be used to measure the scattering intensity as a function of the analyser rotation angle, 2θ, to provide a scan of USAXS or USANS intensity *versus Q*, provided that the mechanical integrity and precision of the analyser angular rotation stage is sufficient for scanning the small angles involved. Because the Q range is scanned in a particular direction, the sample must be rotated azimuthally to obtain any anisotropic microstructural information. The fine Q resolution occurs only in the diffraction plane of the collimating and

---

[1] Certain commercial materials, equipment and references are identified in this paper only to specify adequately experimental procedures. In no case does such identification imply recommendation by NIST nor does it imply that the material or equipment identified is necessarily the best available for this purpose.

analyser monoliths. In the transverse plane, the Q resolution is determined primarily by the angle subtended at the sample position by the detector aperture. This means that the data are intrinsically slit-smeared. While such data can be modelled directly by slit-smearing any model function, the data should be desmeared if they are to be compared with other SAS data measured with a 2D PSD. Fortunately, reliable iterative algorithms are available to accomplish this step, *e.g.* Lake (1967), *provided* that the statistical fluctuations in the data due to noise and other random uncertainties are small compared with genuine features in the scattering curve. If this is not the case, desmearing amplifies these effects, which then appear as artifacts in the desmeared data. In this situation, it is preferable to carry out slit smearing within any interpretation model being considered, and then fit this directly to the slit-smeared data without desmearing the experimental data.

Bonse–Hart USAXS and USANS instruments have developed along somewhat different lines because of the different challenges that have needed to be addressed for acceptable performance to be achieved with X-rays and neutrons. Initially, both USAXS and USANS instruments were developed simply to extend the minimum attainable Q range in SAS measurements to smaller values, and hence extend the microstructure characterization of heterogeneous systems to µm length scales. By combining USAS with SAS measurements it is possible to obtain statistically representative microstructure characterization over a scale range from 10 Å to several µm, while wide-angle scattering and other powder-diffraction methods provide information at the ångstrom scale. Much of the motivation for this comes from a growing realization that processes within material systems occur across length scales with nanoscale phenomena affecting microscale structure and *vice versa*.

USAXS instrumentation has been developed both for laboratory-based use and at synchrotron beamlines. Typically, the collimating and analyser monoliths are set up to accommodate four crystal reflections each. This provides an overall instrumental rocking curve with a full width at half maximum, FWHM, that is approximately equal to the Darwin width for the crystal reflection used [typically Si (111) or Si (220)] and rocking-curve tails that should be much steeper than the fall-off in the USAXS intensity from any sample. In practice, USAXS measurements are extremely sensitive to the state of the crystal surfaces in both monoliths, and careful polishing and etching are required to ensure that neither strain variation nor surface roughness introduce significant artifacts into the USAXS data. Features on the crystal surfaces inevitably contribute some scattering to the instrumental 'blank' runs, but this is not an issue provided such contributions are much less than the genuine USAXS intensity from samples of interest. The point detector is typically a photodiode. With appropriate supporting electronics, this can have a dynamic range in X-ray intensity of more than 10 decades. Thus, at a synchrotron beamline and with precautions to reduce parasitic background effects due to air scattering *etc.*, this is sufficient to measure the intensity profile over the incident beam at $Q = 0$, out into the full SAXS range discussed in the previous section with 2D PSDs in a single USAXS scan. Thus USAXS instruments at a synchrotron can be used in place of SAXS with a 2D PSD, although the signal-to-noise ratio of a well-set-up conventional SAXS instrument is usually better at high Q. The typical Q range of a synchrotron-based USAXS instrument is 0.0001 to 1 Å^{-1}, with the minimum Q also the Q resolution. At the lowest Q values scanned the increment in Q needs to be close to 0.0001 Å^{-1} in order to capture all of the available microstructure information. At larger Q values, the increment can be increased logarithmically to reduce the overall scan times (Ilavsky *et al.*, 2009).

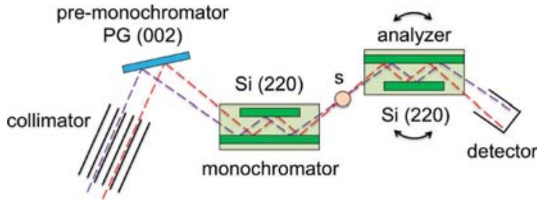

Figure 5.8.4
Schematic of typical USANS configuration at a reactor-based neutron source: s = sample, PG = pyrolitic graphite. Courtesy: J. Barker (NIST Center for Neutron Research).

The high brilliance of third-generation X-ray synchrotrons enables USAXS instrumentation to be developed and enhanced in several ways, some of which are discussed in later sections. However, one modified mode of operation should be mentioned here. While the standard USAXS configuration provides slit-smeared data, the slit smearing can be removed by inserting two transverse crystal pairs, one after the main collimating monolith, and the other before the analyser monolith. This 2D-USAXS configuration is shown in Fig. 5.8.3(*b*). While the USAXS scan still occurs in a single azimuthal direction of **Q**, the data are now unsmeared. Full anisotropic information for a sample can now be obtained by successive USAXS scans with different azimuthal sample orientations.

USANS can extend the SAS Q range to lower minimum Q values than USAXS. This is because the Darwin width of any given crystal's rocking curve for neutron diffraction is intrinsically narrower than for X-rays. However, for many years, the usefulness of USANS was severely limited because of low incident beam flux and the presence of high parasitic background scattering effects. One cause of the background was removed early on by having an odd number of Bragg reflections (usually three) in each crystal pair. This has the effect of removing the instrument from the direct path of parasitic (fast) neutrons coming from the source (Schwahn *et al.*, 1985). However, there remained a major parasitic background contribution, which was ultimately shown to arise from the high penetrating power of neutrons allowing multiple back reflections from the crystals in the collimating and analyser monoliths. In more recent years the problem has been solved by making cuts in the crystals and installing shielding inserts, or otherwise shielding out the contribution from crystal back reflections (Agamalian *et al.*, 1997). While the low incident neutron flux, with respect to X-rays, will probably always limit USANS to providing slit-smeared data in the low-Q regime only, the use of a pyrolitic graphite (PG) pre-monochromator that is convergent in the transverse plane increases the effective incident flux significantly without degrading the instrument performance. With these innovations, very acceptable USANS performance can now be achieved in a Q range from 0.00003 to ~0.005 Å^{-1}, depending on the sample (Barker *et al.*, 2005). This is sufficient to characterize microstructural length scales up to ~30 µm, while also providing overlap with conventional SANS instruments using a 2D PSD, especially with the recent introduction of neutron lenses, discussed in Section 5.8.4. A typical USANS instrument is shown schematically in Fig. 5.8.4. As with USAXS, a point detector is used for USANS, such as a BF_3 gas-filled counter. It must be well shielded against any fast neutron background, and requires sufficient intensity dynamic range to allow scans over the entire incident-beam profile.

5.8.2.3. *Data reduction and calibration of small-angle scattering data*

For all SAS measurements made using transmission geometry, the measured data must be corrected for sample transmission (absorption and other attenuation effects) and for background scattering effects, and then the data must be absolute-calibrated to obtain $d\Sigma/d\Omega$. To do this requires normalizing the scattering intensity to the incident-beam intensity using some monitor detector that provides a measure of the incident-beam intensity (monitor counts) without significantly attenuating it. The monitor counts are usually measured using an ion chamber for SAXS or a fission monitor detector for SANS. X-rays or neutrons, respectively, pass through each of these types of detector with only minimal loss of beam intensity. In the absence of multiple scattering, the sample transmission, T_S, is the ratio of the scattering intensity at $Q = 0$ when the sample is present to that at $Q = 0$ for the empty beam (blank), and is reduced from unity by sample absorption and by all processes in the sample that attenuate the beam *including* SAS. To obtain T_S accurately, the beam intensity is integrated over a region around $Q = 0$ to include the complete profile both of the incident beam (measured without the sample present) and of the transmitted beam measured through the sample.

5.8.2.3.1. *Reduction and calibration of 2D SAS data from a position-sensitive detector*

For a 2D PSD, the intensity, $I_C(i, j)$, in pixel (i, j), normalized to the incident beam and corrected for both electronic background and scattering background effects, is given by (Guinier & Fournet, 1955; Glatter & Kratky, 1982; Kline, 2006; Ilavsky, 2012)

$$I_C(i,j) = \left[\frac{I_S(i,j)}{M_S} - \frac{I_{\rm BGD}(i,j)}{M_{\rm BGD}}\right] - T_S\left[\frac{I_{\rm EB}(i,j)}{M_{\rm EB}} - \frac{I_{\rm BGD}(i,j)}{M_{\rm BGD}}\right], \qquad (5.8.3)$$

where $I_S(i, j)$, $I_{\rm BGD}(i, j)$ and $I_{\rm EB}(i, j)$ are the measured intensities for the sample, the electronic (beam off) dark current background and the empty beam runs, respectively; M_S, $M_{\rm BGD}$ and $M_{\rm EB}$ are the corresponding monitor counts for the incident beam, and T_S is the sample transmission, as defined above. The normalized $I_C(i, j)$ data then need to be calibrated and converted to $d\Sigma/d\Omega$. To do this, the position of the incident beam on the 2D PSD must be determined. This defines the PSD pixel for which $2\theta = Q = 0$. Using the instrument configuration geometry, the scattering angle and azimuthal angle for all other (i, j) pixels can be determined, and hence the corresponding $\mathbf{Q}_{ij}$. In order to complete the intensity calibration and convert the $I_C(i, j)$ or $I_C(\mathbf{Q}_{ij})$ to $d\Sigma/d\Omega$, we can apply from first principles the following relation:

$$\frac{d\Sigma}{d\Omega}(\mathbf{Q}_{ij}) = \frac{I_C(\mathbf{Q}_{ij})}{I_{\rm EB}(0)}\left(\frac{1}{T_{\rm SS}\tau_S\Delta\Omega}\right), \qquad (5.8.4)$$

where $I_{\rm EB}(0)$ is the incident-beam intensity at $Q = 0$ measured under the same conditions as for the sample, τ_S is the sample thickness and $\Delta\Omega$ is the solid angle subtended at the sample by one detector element. For SAS absolute intensity calibration purposes, the sample transmission, $T_{\rm SS}$ in equation (5.8.4), should *exclude* any incident-beam attenuation due to SAS itself. In most practical cases, $T_{\rm SS} \simeq T_S = I_C(0)/I_{\rm EB}(0)$, and the actual measured sample transmission, T_S, can be used in equation (5.8.4) in place of $T_{\rm SS}$. However, if significant multiple scattering is present, the measured $T_S < T_{\rm SS}$, and a multiple-scattering correction must be made (see Section 5.8.2.3.3).

Unfortunately, for most conventional SAS measurements using a 2D PSD, the detector does not have sufficient dynamic range to measure the incident-beam intensity and frequently it must be protected by a beam stop from damage due to exposure to the full incident-beam intensity during SAS measurements. To measure T_S, attenuators are required to protect the PSD during both the sample and empty beam measurements. Nowadays, the accepted best practice is to calibrate the attenuators, and simply multiply the right-hand side of equation (5.8.4) (using the measured T_S in place of $T_{\rm SS}$) by the inverse of the calibrated attenuation factor. However, the intensity calibration can also be carried out using a calibration standard sample. A 'primary' calibration standard may be used, calibrated using the primary (first-principles) relation described in equation (5.8.4) at a SAS instrument where the detector can indeed withstand the full incident-beam intensity. The SAS intensity is then measured at any other instrument for both the standard and the sample(s) of interest. The intensity factor required to put the standard's measured scattering intensity onto its known absolute scale is determined, and this same factor is then used to calibrate data from any 'unknown' sample. A recently established standard of this kind is the NIST Standard Reference Material SRM 3600, which is a SAXS intensity calibration standard based on glass carbon (Allen *et al.*, 2017). Alternatively, a 'secondary' standard can be used, such as a monodispersed silica sphere suspension of known volume concentration. The SAS data can be fitted using one of the models discussed in Section 5.8.3 such as the Guinier approximation, and the data calibrated from the fit result.

Finally, 2D PSD SAS data can be sector-averaged over an azimuthal range to give $d\Sigma/d\Omega$ as a function of $\mathbf{Q}$, where the $\mathbf{Q}$ direction is associated with the mean azimuthal angle of the sector. More usually, when the scattering is circularly symmetric about the incident-beam direction, the data are circularly averaged to give $d\Sigma/d\Omega$ as a function of Q.

5.8.2.3.2. *Reduction and calibration of 1D USAXS or USANS data*

For 1D USAS data, the 2D (i, j) indexing can be replaced from the outset by a 1D indexing of Q values, with the direction of $\mathbf{Q}$ defined by the plane of the instrument's diffraction optics and by the direction of scanning. In USAS measurements it is important that the scattering profile is measured over the centre of the rocking-curve peak in order to establish accurately where $Q = 0$. All other Q values are measured relative to this to give $I_C(Q)$ after applying a 1D form of equation (5.8.3). In both USAXS and USANS instruments, the detector has sufficient intensity dynamic range to measure the incident-beam intensity directly, so that $I_C(Q)$ can be converted to $d\Sigma(Q)/d\Omega$ using a 1D form of equation (5.8.4). For USAS measurements, $\Delta\Omega$ is the product of the angle subtended at the sample by the slit length in the direction transverse to the diffraction plane and the Darwin-based angular diffraction width in the diffraction plane. In the usual case of 1D USAXS or USANS, the calibrated $d\Sigma/d\Omega$ is slit-smeared and should be desmeared as described in Section 5.8.2.2.

5.8.2.3.3. *Corrections for multiple scattering and flat background*

A correction must be applied to the calibration when significant multiple-scattering effects are present. In the case of copious multiple SAS, there is significant broadening of the X-ray or neutron beam profile transmitted through the sample (*i.e.*, no unscattered beam survives passage through the sample). This situation is usually associated with a high concentration of strongly scattering coarse features, and a specialized analysis is required (Berk & Hardman-Rhyne, 1985, 1988). For the usual case, where the SAS remains distinguishable from the transmitted beam profile but where the total probability of small-angle scattering is greater than 5–10% of the incident beam, a more subtle correction suffices. Schelten & Schmatz (1980) developed a treatment of this situation that is still widely used at SANS facilities, but can also be applied to SAXS. In fact, any distortion of the scattering profile at low Q due to multiple scattering cannot easily be corrected. However, an intensity correction may be made that at least calibrates the intensity correctly for data at higher Q values. In this situation, T_S, measured simply from the ratio $I_C(0)/I_{\rm EB}(0)$, while remaining correct for subtracting out scattering from the blank in equation (5.8.3), is significantly underestimated for use in the calibration equation (5.8.4). It should be replaced with a corrected (larger) transmission, $T_{S\ \rm corr}$, which is obtained by integrating $I_C(Q)$ and $I_{\rm EB}(Q)$ from $Q = 0$ out to a Q value beyond which multiple scattering is negligible for the sample being studied. The ratio of the integrals then gives $T_{S\ \rm corr}$ [$= T_{\rm SS}$ in equation (5.8.4)].

Finally, many samples show flat background-scattering contributions in addition to the true SAS contribution. For X-rays, this arises from parasitic scattering contributions such as air scattering or scattering from the windows of the sample cell. For neutrons, incoherent flat background scattering results from the difference in the neutron interaction with a nuclide depending on whether the neutron and nuclear spins are parallel or anti-parallel. The average of the two cases gives rise to the coherent scattering on which SANS and ND are based. The spatially random fluctuations between the two cases leads to an incoherent flat background. For X-rays or neutrons, the flat background scattering should be subtracted out before applying the various interpretation models described in Section 5.8.3. If the flat background scattering is obvious at high Q, it can be directly subtracted out. If not, it can sometimes be determined by fitting the Porod scattering at high Q (see Section 5.8.3.1.2).

5.8.2.4. *Reflectivity, grazing-incidence small-angle scattering and diffraction*

All of the SAS methods discussed in previous sections assume transmission measurement geometry, but this precludes a major class of heterogeneous material systems of increasing technological importance: thin-film microstructures on a substrate. For such systems SAS and related measurements in reflection geometry are of interest. X-ray and neutron reflectivity (XRR and NR), where $\mathbf{Q}$ is perpendicular to the substrate, provide depth-dependent structural information for a thin film (Parratt, 1954). Grazing-incidence SAXS and SANS (GI-SAXS and GI-SANS), and, utilizing the high penetrating power of neutrons for thicker layers and coatings, near-surface SANS (NS-SANS) can provide microstructural information both as a function of film depth and within the plane of the film (Levine *et al.*, 1991; Hamilton *et al.*, 1996). Owing to the greater penetrating power of neutrons, NR and NS-SANS are more applicable to thicker coatings or to buried interfaces than are XRR or GI-SAXS, which are more applicable to thin films. The lower penetrating power of X-rays is frequently an advantage where information is sought on disordered or ordered structures within a film without the reflectivity or scattering data being affected by contributions from the substrate. Although NR and NS-SANS can provide important information in certain situations, thicker coatings *etc.* can usually be removed from the substrate for analysis, in section or in plane, using transmission geometry (at least with X-rays). However, thin films 10 Å to a few hundred ångstroms thick (which may or may not be disordered in nature) cannot usually be removed from the substrate, and must be studied with X-rays rather than neutrons. So, in this section, we concentrate on XRR and GI-SAXS.

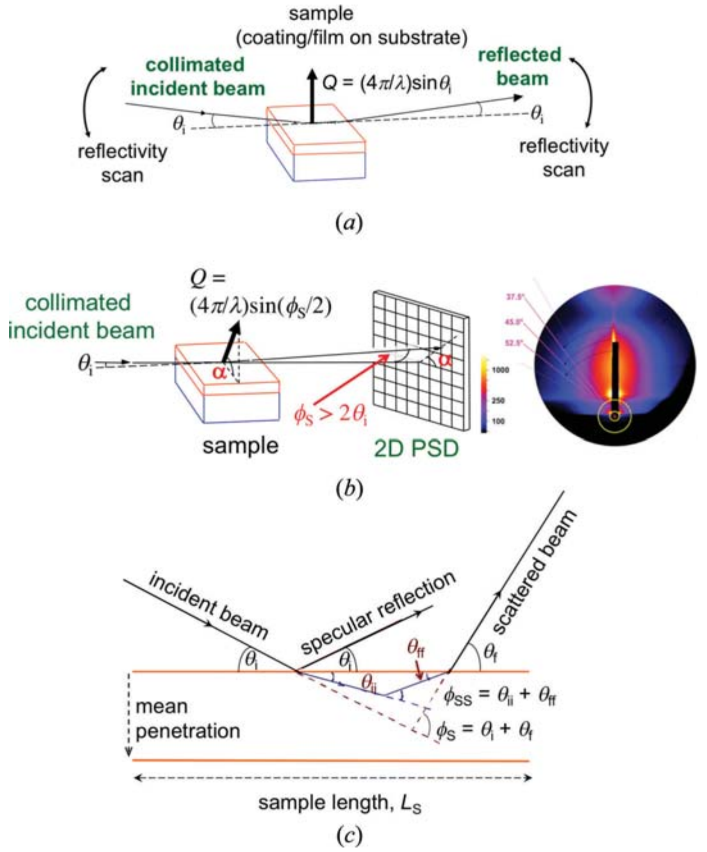

Figure 5.8.5
(*a*) Schematic of basic reflectivity measurement geometry for XRR or NR. (*b*) Schematic derived from Green *et al.* (2009) for GI-SAXS also showing typical 2D GI-SAXS data with sector averages. (*c*) Refraction and reflection geometries for GI-SAXS or NS-SANS, as discussed in the text.

Fig. 5.8.5(*a*) shows a schematic of the basic measurement geometry for XRR or NR, while Fig. 5.8.5(*b*) presents a corresponding schematic for GI-SAXS or NS-SANS. For specular reflectivity the direction of $\mathbf{Q}$ is perpendicular to the substrate plane and so information is obtained on through-thickness features, as well as effects due to surface roughness. In GI-SAXS or NS-SANS, components of $\mathbf{Q}$ are both perpendicular to the substrate ($\mathbf{q}_z$) and, depending on the azimuthal angle α, parallel to the substrate ($\mathbf{q}_y$). Thus, in-plane microstructure information is obtainable.

In reflectivity measurements, the intensity of the reflected beam is measured as a function of the incident angle, θ_i ($= \theta_r$). In a reflectivity scan the sample is rotated through θ_i angles from 0° to the maximum θ_r ($\theta_{r\rm MAX}$) for which a measurable reflected beam intensity can be detected, while the detector angle, $2\theta_r$, is rotated from 0° to $2\theta_{r\rm MAX}$. In principle, the reflectivity, $R(\theta_r)$, can be defined as $R(\theta_r) = I(\theta_r)/I(0)$, where $I(\theta_r)$ and $I(0)$ are the measured intensities of the reflected beam for θ_r and for 0°, respectively. In practice, the increasing length of the beam footprint on the sample for decreasing $\theta_i = \theta_r$ values results in a loss of reflected intensity once the footprint is longer than the sample dimension in the reflection plane, requiring a correction to be made for the consequent loss in intensity actually incident on the sample. Furthermore, for a well aligned sample geometry at $\theta_r = 0°$ the sample, seen edge-on, absorbs half of the incident beam while the other half of the incident beam does not impinge on the sample at all. Thus, direct measurement of $I(0)$ requires removal of the sample. Once corrected, $R(\theta_r) = 1$ for θ_i ($= \theta_r$) $< \theta_C$, where θ_C is the critical angle for total reflection given by $\theta_C = \lambda\{|\Delta\rho|/\pi\}^{1/2}$ and $|\Delta\rho|$ is the difference in scattering-length density across the reflecting interface. Corrected reflectivity data for $R(\theta_r)$ *versus* θ_r over sufficient angular range, and with sufficient angular resolution, must be obtained to capture the structural information associated with the thin-film layer(s). For practical purposes, laboratory-based X-ray sources can provide the required dynamic range in $R(\theta_r)$ for XRR measurements of films thicker than ~100 Å. For thinner films, measurements at least at a first-generation synchrotron are required, and it is usually necessary to determine the reflectivity curve from the surface of the bare substrate in order to correct for any substrate artifacts not associated with the thin-film structure of interest. Frequently, it is convenient to convert the θ_r values to Q [$= (4\pi/\lambda)\sin\theta_r$] and do further analysis on corrected data for $R(Q)$ *versus* Q, together with uncertainties in $R(Q)$.

In GI-SAXS or NS-SANS measurements the sample is oriented at a fixed grazing incident angle, θ_i, to the incident-beam direction ($\theta_i > \theta_C$ for scattering from within the film) and the data are collected using a 2D PSD as for conventional transmission geometry SAXS or SANS. Measurements can be made using different values of θ_i, and the different 2D scattering data analysed to determine how the film microstructure changes with depth. By reducing θ_i below θ_C, it can be established whether the microstructure that causes the scattering is within the film or is located on the surface. The location where the incident beam impinges on the sample (required for calculating where $Q = 0$ on the 2D detector), as well as the parasitic scattering contribution, can only be determined by moving the sample out of the beam. With the sample in place, both the incident beam and scattering that would be in the sample shadow as viewed from the 2D detector are occluded and unobservable. Also, the specularly reflected incident beam further obscures the data at low Q, and effectively increases the minimum observable Q. Refraction corrections must be applied to both the incident and scattered X-ray or neutron beam directions, and normalization to obtain $d\Sigma/d\Omega$ is complicated both by the complex effective sampling volume and the need to apply the distorted-wave Born approximation (DWBA) in the data reduction and analysis when multiple reflection and scattering contributions exist (Sinha *et al.*, 1988).

For a thick film of refractive index n, given by $n^2 = 1 - \theta_C^2$, Fig. 5.8.5(*c*) illustrates the situation for scattering in the refraction plane. For an external grazing-incidence angle θ_i, an external scattered grazing angle θ_f and apparent scattering angle φ_S ($= \theta_i + \theta_f$), measured outside the film, the corresponding angles inside the film are θ_{ii}, θ_{ff} and φ_{SS} ($= \theta_{ii} + \theta_{ff}$), where $\theta_{ii}^2 = \theta_i^2 - \theta_C^2$ and $\theta_{ff}^2 = \theta_f^2 - \theta_C^2$. For a finite azimuthal angle α, the outgoing scattered grazing angles are reduced to θ_2 and θ_{22} where $\theta_2 = \theta_f\cos\alpha$ and $\theta_{22}^2 = \theta_2^2 - \theta_C^2$. Refraction effects cause corresponding changes in the components of $\mathbf{Q}$. While the component parallel to the substrate, q_P, is the same inside or outside the film, *i.e.* $q'_P = q_P$, the component normal to the film, q_N, is changed by the refraction at the film boundary, so that inside the film $q'_N = q_N[\cos\theta_i(\sin\theta_{ii} + \sin\theta_{22})]/[\cos\theta_{ii}(\sin\theta_i + \sin\theta_2)]$ and Q' inside the film is given by $Q'^2 = Q^2 - q_N^2 + q'^2_N$, where Q is the apparent external value. The refraction causes all terms in the SAS expressions to change and for a thick film (where reflection from the film/substrate interface can be ignored) it can be shown that inside the film

$$\frac{d\Sigma'}{d\Omega'}(Q') = \left[\cot\theta_{ii} + \cot\theta_{22}\right]\left(\frac{\sin\theta_{22}}{\sin\theta_2}\right)\left(\frac{1}{T_S\sin\theta_{ii}}\right) \times \left[\frac{(\sin\theta_i + n\sin\theta_{ii})}{\sin\theta_i}\right]^2 \frac{d\Sigma}{d\Omega}(Q), \qquad (5.8.5)$$

where $T_S = 2[\exp(-\Sigma_T L_S) + \Sigma_T L_S - 1]/(\Sigma_T L_S)^2$ is the theoretical transmission of the sample film of length L_S along the beam direction and it is assumed that the film material has a total attenuation cross section of Σ_T. The value of Σ_T determines whether a film of thickness $\tau_{\rm film}$ can be considered thick or whether it must be treated as a thin film with the full DWBA formalism applied. The maximum penetration depth, $\zeta_{\max}$, measurable for a given scattering geometry is given by $\zeta_{\max} = L_S/[\cot\theta_{ii} + \cot\theta_{22}]$. However, the mean penetration depth $\zeta_{\rm mean} = \zeta_{\max}(1/\Sigma_T L_S)[2 + \Sigma_T L_S - (2/T_S)]$. While generally $\zeta_{\rm mean} \ll \zeta_{\max}$, the criterion for a thick film is that $\zeta_{\rm mean} \ll \tau_{\rm film}$.

5.8.2.5. *Wide-angle scattering and other methods for disordered structures*

As mentioned in Section 5.8.1, a heterogeneous material system may contain crystalline components even if the heterogeneous arrangement of those components is itself disordered. For the SAS and reflectivity measurements discussed in Section 5.8.2.4, a fully quantitative analysis is only possible if the elemental composition and density of each of the components are known. This information is required in order to determine accurately the $|\Delta\rho|^2$ contrast-factor term in equation (5.8.2*a*). Thus, wide-angle and powder-diffraction measurements that enable any component crystalline phases to be identified can play a critical role. General powder-diffraction characterization is covered elsewhere in this volume. However, when *in situ* studies of a disordered material undergoing some change in real time are of interest, the use of WAXS and WANS to monitor specific diffraction peaks associated with crystalline phases that may be present, even if only transitory in nature, can provide key information. Several combined SAXS/WAXS instruments have been developed at third-generation X-ray synchrotron-radiation sources to enable the simultaneous study of microstructure evolution and the appearance or disappearance of crystalline phases within the microstructure (Lai *et al.*, 2006).

Finally, some attention must be given to total-scattering methods that have evolved in recent years to interrogate the short-range or limited-range crystalline structure that can be encountered in disordered materials. These have evolved from earlier 'liquids amorphous' methods (mainly neutron-based) to quantify structure in materials with little or no crystalline structure, such as glasses (Price, 1999). However, these methods now extend to a wide range of nanocrystalline or poorly crystalline materials. The basis of such measurements is to collect contiguous data over a very large Q range with sufficient resolution and intensity throughout the Q range to quantify the degree and scale range of structure present. These requirements tend to confine such instruments to third-generation X-ray synchrotrons and pulsed-neutron-source facilities that can accommodate long beamlines. However, these instruments are now making significant progress in interrogating the whole range of disordered materials at the structural level (Billinge & Levin, 2007; see also Chapter 5.7).

For powder-diffraction studies, the coherent diffraction intensity, $I_{\rm coh}$, from an ensemble of N atoms is given by (Warren, 1990; Farrow & Billinge, 2009)

$$I_{\rm coh} = \sum_{i,j} b_j^* b_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}) = N\langle b^2\rangle + \sum_{i\neq j} b_j^* b_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}), \tag{5.8.6}$$

where b_i and b_j are the neutron scattering lengths or X-ray form factors per atom at sites i and j, respectively, $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$, b^* denotes a complex conjugate as a function of $\mathbf{Q}$, and $\langle b^2\rangle$ is the mean-square value of b_i or b_j. The total-scattering structure factor per atom, $S(\mathbf{Q})$, describes the scattering between the atoms in an ensemble, and is given by

$$S(\mathbf{Q}) = 1 + \frac{\sum_{i\neq j} b_j^* b_i \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij})}{N\langle b\rangle^2}, \tag{5.8.7}$$

where $S(\mathbf{Q}) = 1$ for isolated atoms. We note that, for neutrons, b_i and b_j are isotropic and independent of Q for scattering from the nucleus. For X-ray scattering or magnetic neutron scattering from the atomic electron distribution a correction is required at high Q because of the finite size of the atom, but this can be neglected at least for the forward scattering. Thus, for an isotropic microstructure, the Debye relation that the orientational average of $\exp(i\mathbf{Q}\cdot\mathbf{r}_{ij})$ is equal to $\sin(Qr_{ij})/Qr_{ij}$ can be used to give

$$S(Q) - 1 = \left(\frac{1}{N\langle b\rangle^2}\right) \sum_{i\neq j} b_j^* b_i \left[\frac{\sin(Qr_{ij})}{Qr_{ij}}\right]. \tag{5.8.8}$$

The Q dependence can be removed from everything except for the sine term by using the reduced total-scattering structure factor, $S_{\rm RT}(Q)$, where

$$S_{\rm RT}(Q) = Q[S(Q) - 1] = \left(\frac{1}{N\langle b\rangle^2}\right) \sum_{i\neq j} b_j^* b_i \left[\frac{\sin(Qr_{ij})}{r_{ij}}\right]. \tag{5.8.9}$$

The sine Fourier transform of $S_{\rm RT}(Q)$ gives the real-space function $G(r)$, where

$$G(r) = (2/\pi) \int\limits_0^\infty S_{\rm RT}(Q) \sin(Qr)\,{\rm d}Q, \tag{5.8.10}$$

and by substituting equation (5.8.10) into equation (5.8.9), we get (for positive r)

$$G(r) = \left(\frac{1}{rN\langle b\rangle^2}\right) \sum_{i\neq j} b_j^* b_i \delta(r - r_{ij}), \tag{5.8.11}$$

where $\delta(x)$ denotes a Dirac delta function. It is clear that $G(r)$ is a pair density distribution function, as can be shown by considering the case of an ensemble of N identical atoms:

$$\int\limits_a^b G(r) r\,{\rm d}r = N_{ab} = \int\limits_a^b 4\pi r^2 n(r)\,{\rm d}r, \tag{5.8.12}$$

where N_{ab} is the number of atoms found between a radius $r = a$ and a radius $r = b$, measured from any one atom, and $n(r)$ is the atomic number density distribution measured similarly as a function of r, thus allowing a radial distribution function, $Y(r)$, to be defined by $Y(r) = 4\pi r^2 n(r)$.

Algorithms now exist to extract $G(r)$ *versus* r from measured $I_{\rm coh}$ data *versus* Q, *via* the derived $[S(Q) - 1]$ and $S_{\rm RT}(Q)$ functions (Juhás *et al.*, 2013). Fig. 5.8.6 shows both typical total-scattering $[S(Q) - 1]$ (model) data *versus* Q and the derived atomic pair distribution function, $G(r)$ *versus* r. In practice, the inverse Fourier sine transform of equation (5.8.10) has finite Q limits. In particular, there is always a finite minimum Q for which the scattering and hence $S(Q)$ can be measured. Loss of the non-measurable scattering contribution near $Q = 0$ leads to a subtraction from the calculated pair distribution function, $G(r)$, that can be associated with the scattering from structure at large r. In the case of a uniform bulk material microstructure, including many glasses, the subtracted component is simply related to the averaged atomic scattering-length density, n_0, applicable over large distances, and it can be shown that (Cargill, 1971; Farrow & Billinge, 2009)

$$G(r) = 4\pi r\big[n(r) - n_0\big]. \tag{5.8.13}$$

Disordered structures can be evaluated using equations (5.8.6)–(5.8.13) in the case of bulk materials. However, when the disordered elements themselves comprise an ensemble of nanocrystalline features, the $-4\pi r n_0$ term becomes more complex; this situation is discussed further in the next section.

Meanwhile, noise in the WAXS data at high Q can cause oscillatory artifacts to appear in the $G(r)$ function because of data truncation at a finite maximum Q. These can be removed by smoothing the data, but this still results in some loss of information in the extracted $G(r)$ function if the level of smoothing required either significantly exceeds that due to finite instrument resolution in Q, or it reduces peak intensities significantly more

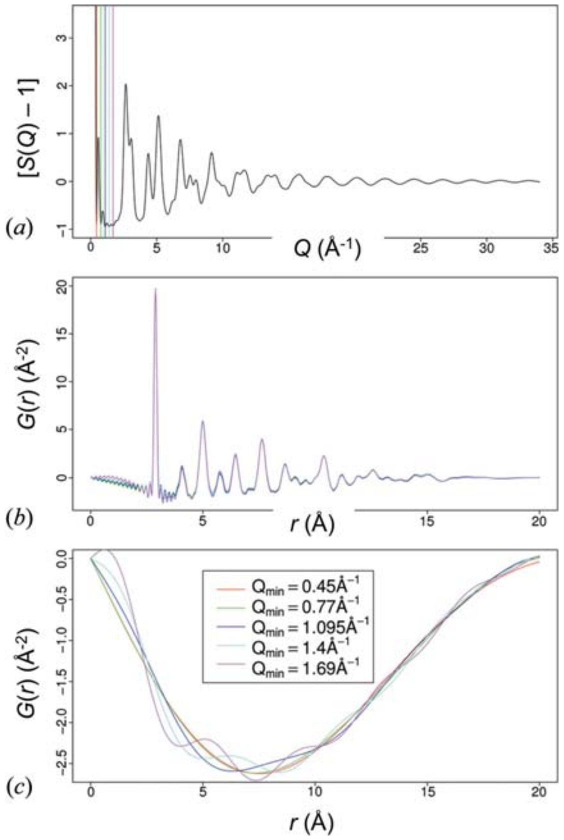

Figure 5.8.6

(*a*) Schematic of typical total-scattering $[S(Q) - 1]$ data *versus* Q for model Au core–shell nanoparticles. Choices of partition between small- and wide-angle scattering are marked by vertical lines. (*b*) The corresponding atomic pair density distribution function, $G(r)$, *versus* r, obtained *via* Fourier transform of wide-angle scattering data only, starting from various minimum Q values ($Q_{\rm min}$). (*c*) The Fourier transform of data in the SAS range from $Q = 0$ to $Q = Q_{\rm min}$ for various $Q_{\rm min}$. The $-4\pi r n_0$ term of equation (5.8.13) arising from the non-measurable scattering at $Q = 0$ is visible at low Q, but the rest of the function is related to $\gamma_0(r)$ described in Section 5.8.3.2 for nanoparticle scattering. Adapted from Mullen & Levin (2011).

than the Debye–Waller effect (see Section 5.8.3.3) of thermal diffuse scattering (Toby & Egami, 1992).

5.8.3. Quantitative analysis of disordered heterogeneous materials

In Section 5.8.2 we have set out the main experimental measurement techniques, the kind of data obtainable and how the data should be reduced to provide information on the sample material system of interest. In this section we consider how such data should be interpreted to quantify actual structural and microstructural parameters of interest for disordered material systems. It is not possible to cover every interpretative scheme in existence, but the main classes of interpretative schemes and models are reviewed to give a sense of the range of analyses possible.

5.8.3.1. *Interpretative models for analysis of SAS data*

5.8.3.1.1. *Guinier approximation*

Assuming any flat background scattering has been subtracted, the heterogeneous system is sufficiently disordered and dilute that the structure-factor term, $S(Q)$, in equation (5.8.2*a*) can be assumed to be unity and the inhomogeneities are approximately monodispersed in size and shape, perhaps the simplest interpretative approximation for SAS data is the Guinier approximation (Guinier & Fournet, 1955):

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V|\Delta\rho|^2 V_P \exp\left(-\frac{Q^2R_G^2}{3}\right), \quad QR_G < {\sim}1, \qquad (5.8.14)$$

where R_G is the Guinier radius (mean radius of gyration) of the scattering features. For spherical particles or voids of radius R_P, $R_G^2 = 3R_P^2/5$ and $V_P = 4\pi R_P^3/3$. While the approximation is only valid for $QR_G < {\sim}1$, equation (5.8.14) clearly shows how the width of the scattering profile is inversely related to the size of the scattering features. We also note that the SAS intensity is proportional both to the volume fraction of scattering features present and to their individual mean volumes. Thus, SAS methods will be strongly volume-weighted over any size distribution of inhomogeneities that may actually be present.

5.8.3.1.2. *Porod scattering regime*

At high Q values the SAS intensity can be related to the specific surface area of the scattering features (Porod, 1951, 1952):

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \frac{2\pi|\Delta\rho|^2 S_V}{Q^4} + \mathrm{BGD}, \quad QR_G \gg 1, \qquad (5.8.15)$$

where S_V is the surface area per unit sample volume and BGD is any residual flat background scattering that needs to be considered at high Q where the true SAS scattering intensity is weak. Frequently, it is convenient to plot $Q^4\,\mathrm{d}\Sigma/\mathrm{d}\Omega$ *versus* Q^4 for high Q and fit a straight-line slope of gradient BGD and intercept $2\pi|\Delta\rho|^2 S_V$. (Note that this provides a means of determining the flat background, BGD.) Thus, just as equation (5.8.14) provides information on the volume fraction of the inhomogeneities in a disordered system, equation (5.8.15) provides the corresponding surface-area information – provided that the contrast factor, $|\Delta\rho|^2$, is known. Even when $|\Delta\rho|^2$ is not known, the ratio of the two front terms of these equations provides the surface area per unit volume of the individual inhomogeneities themselves, because $|\Delta\rho|^2$ cancels out.

5.8.3.1.3. *Scattering invariant*

The volume fraction of the inhomogeneous features giving rise to SAXS or SANS can be more generally related to the overall scattering through the so-called scattering invariant (Glatter & Kratky, 1982), which is essentially the SAS intensity integrated over all **Q**:

$$2\pi^2\Phi_V(1-\Phi_V)|\Delta\rho|^2 = \int\limits_0^\infty Q^2\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega}(Q)\,\mathrm{d}Q, \qquad (5.8.16)$$

where the integral is taken over all Q values (equivalent to scattering over a 4π solid angle). In principle, if $|\Delta\rho|^2$ is known, the volume fraction of the scattering features, Φ_V, can be determined independently of the specific morphology or disordered arrangement. Experimentally, the integrand on the right-hand side of equation (5.8.16) must usually be extrapolated beyond the measured Q range, both at low Q and at high Q where the Q^2-weighted SAS intensity is weak and a careful flat background subtraction must be made.

5.8.3.1.4. *Debye–Bueche model*

While many disordered material systems contain discrete particles or pores that comprise the inhomogeneities giving rise to SAS, this is not necessarily the case. For example, polymer blends may contain separate (non-mixing) phases separated by an interface that permeates throughout the sampling volume. Assuming the two phases (1 and 2) permeate the sampling volume randomly with a characteristic (Debye) length ξ, then it can be shown that the scattering is given by (Debye & Bueche, 1949)

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \frac{8\pi\xi^3\Phi_{1V}\Phi_{2V}|\Delta\rho|^2}{(1+Q^2\xi^2)^2}, \qquad (5.8.17)$$

where Φ_{1V} and Φ_{2V} are the volume fractions of the two phases ($\Phi_{1V} + \Phi_{2V} = 1$) and $|\Delta\rho|^2$ is the scattering contrast factor between phases 1 and 2. Assuming that $|\Delta\rho|^2$ is known, a Lorentzian function can be fitted to obtain ξ from the intensity variation in Q, then Φ_{1V} and Φ_{2V} determined from the absolute scattering intensity, together with the constraint that they must sum to unity. We also note that, in the limit of high Q, equation (5.8.17) gives Porod Q^{-4} scattering, and the surface area, S_v, so obtained can be related to the variables Φ_{1V}, Φ_{2V} and ξ determined by $S_v = 4\Phi_{1V}\Phi_{2V}/\xi$.

5.8.3.1.5. *Shape effects in the form factor*

As we have indicated, equations (5.8.14) and (5.8.15) provide working approximations for the scattering intensity at low Q and at high Q for a dilute population of randomly oriented scattering features. However, analytical expressions have been established for the scattering intensity at all Q for dilute populations of randomly oriented scattering features of specific shape that are also monodispersed in size and shape. For example, see Pedersen (1997). Here we summarize a few of the more significant generic expressions for $\mathrm{d}\Sigma/\mathrm{d}\Omega$ associated with scattering features of specific shape (also see Fig. 5.8.7):

(i) *Spheroidal features of orthogonal radii R_O, R_O, βR_O* (Shull & Roess, 1947; Roess & Shull, 1947):

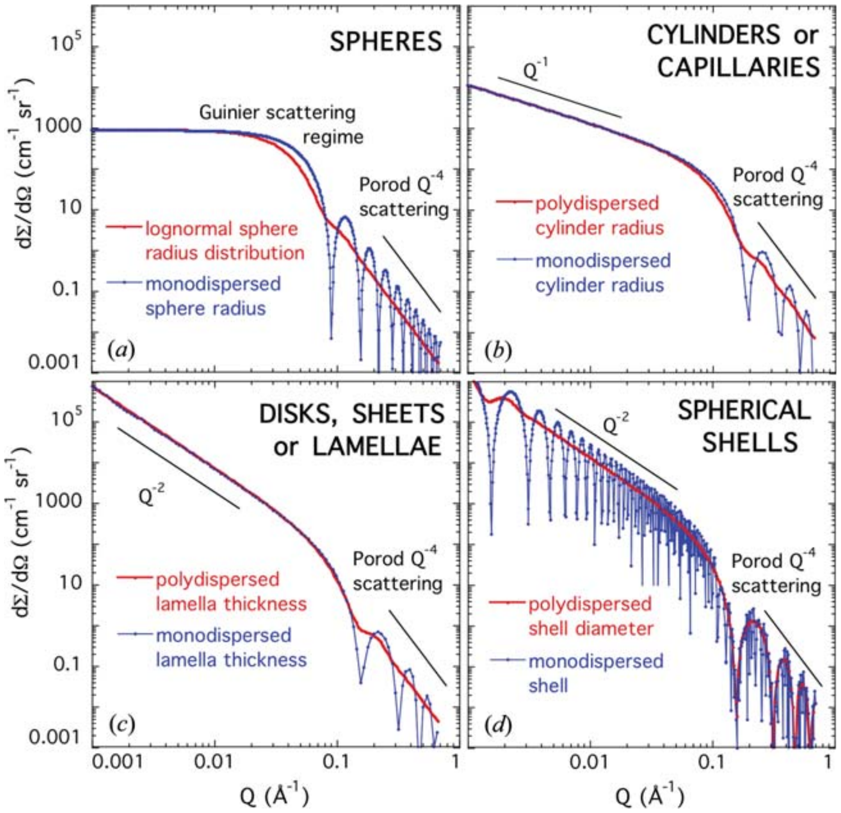

Figure 5.8.7

Characteristic SAS intensity profiles of ensembles of scattering features, both monodispersed and polydispersed in size. (*a*) Spheres of mean diameter 100 Å; (*b*) cylinders or capillaries of mean diameter 40 Å and length 4000 Å; (*c*) discs or lamellae of mean thickness 40 Å and diameter 4000 Å; and (*d*) spherical shells of mean diameter 4000 Å and fixed shell thickness 40 Å. Porod scattering and other characteristic power laws are indicated. Note that 20% polydispersity in size is sufficient to eliminate much of the Bessel-function oscillation found in the scattering from monodispersed features. Functions are derived using software developed by S. R. Kline of NIST Center for Neutron Research (Kline, 2006).

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V|\Delta\rho|^2 V_P \frac{9\pi}{2}\int_0^1 \frac{\left[J_{3/2}(u)\right]^2}{u^3}\,\mathrm{d}X, \qquad (5.8.18)$$

where $V_P = 4\pi\beta R_O^3/3$, the ordinary Bessel function $J_{3/2}(u) = (2/\pi)^{1/2}(\sin u - u\cos u)/u^{3/2}$, $u = QR_O K(\beta, X)$, $K(\beta, X) = [1 + (\beta^2 - 1)X^2]^{1/2}$, $X = \cos\eta$, and η is the angle between the direction of **Q** and the βR_O axis of the spheroid. In the case of $\beta = 1$ we get for spherical features

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V|\Delta\rho|^2 V_P \left[3\left(\frac{\sin(QR_O) - QR_O\cos(QR_O)}{(QR_O)^3}\right)\right]^2. \qquad (5.8.19)$$

The average intensity of the Bessel function oscillations in equations (5.8.18) and (5.8.19) can be approximated as a function of Q: in the small-Q regime by equation (5.8.14) where $R_G^2 = (2 + \beta^2)R_O^2/5$, and in the large-$Q$ regime by equation (5.8.15) where, for a spheroid,

$$S_V = \frac{3\Phi_V \chi_S}{R_O} \qquad (5.8.20a)$$

$$\chi_S = \frac{1}{2\beta}\left\{1 + \frac{\beta^2}{(1-\beta^2)^{1/2}}\ln\left[\frac{1 + (1-\beta^2)^{1/2}}{\beta}\right]\right\} \quad \beta \le 1, \qquad (5.8.20b)$$

$$\chi_S = \frac{1}{2\beta}\left\{1 + \frac{\beta^2}{(\beta^2-1)^{1/2}}\arcsin\left[\frac{(\beta^2-1)^{1/2}}{\beta}\right]\right\} \quad \beta \ge 1, \qquad (5.8.20c)$$

and we note that $\chi_S = 1$ for $\beta = 1$.

(ii) *Discs, sheets or laminar pores of diameter $2R_D$ and thickness τ_D, where $\tau_\Delta \ll 2R_D$* (Guinier & Fournet, 1955; Glatter & Kratky, 1982). Again, assuming a dilute ensemble of randomly oriented scattering features, it can be shown that

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V|\Delta\rho|^2 V_P \int_0^1 \left| 2J_O\left(\frac{Q\tau_D X}{2}\right)\frac{J_1\left[QR_D(1-X^2)^{1/2}\right]}{QR_D(1-X^2)^{1/2}}\right|^2 \mathrm{d}X, \qquad (5.8.21a)$$

where $X = \cos\eta$ and η is the angle between the axis of the disc and the direction of **Q**, here $V_P = \pi R_D^2\tau_D$, and the spherical Bessel functions are given by $J_0(u) = \sin u/u$ and $J_1(v) = (\sin v - v\cos v)/v^2$. Equation (5.8.21*a*) is in fact valid for all values of τ_D and R_D, but for $\tau_D \ll 2R_D$ and neglecting the Bessel-function oscillations, the scattering intensity follows a Q^{-2} power law in the regime $R_D^{-1} \ll Q \ll 2\tau_D^{-1}$ and a Q^{-4} Porod power law for $Q \gg 2\tau_D^{-1}$. For near-infinitesimal τ_D, $\mathrm{d}\Sigma/\mathrm{d}\Omega$ is given by

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V|\Delta\rho|^2 V_P\left[1 - \frac{J_1(2QR_D)}{QR_D}\right]\frac{2}{(QR_D)^2}, \qquad (5.8.21b)$$

where the spherical Bessel function $J_1(v) = (\sin v - v\cos v)/v^2$ and there is no Porod Q^{-4} scattering. The terminal slope $\simeq Q^{-2}$ for $Q \gg R_D^{-1}$. There is, however, a Guinier regime at low Q with $R_G^2 = R_D^2/2$.

(iii) *Cylinders, rods or capillary pores of radius r_C and length L, where $L \gg 2r_C$* (Guinier & Fournet, 1955; Glatter & Kratky, 1982):

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V |\Delta\rho|^2 V_P \int\limits_0^1 \left| 2J_O\left(\frac{QLX}{2}\right) \frac{J_1\left[Qr_C(1-X^2)^{1/2}\right]}{Qr_C(1-X^2)^{1/2}} \right|^2 \mathrm{d}X, \tag{5.8.21c}$$

where $X = \cos\eta$ and η is the angle between the axis of the cylinder and the direction of $\mathbf{Q}$; here $V_P = \pi {r_C}^2 L$, and the spherical Bessel functions are given by $J_0(u) = \sin u/u$ and $J_1(v) = (\sin v - v\cos v)/v^2$. Again, equation (5.8.21c) is valid for all r_C and L, and is in fact mathematically identical to equation (5.8.21a). However, for $L \gg 2r_C$ and neglecting the Bessel-function oscillations, the scattering intensity follows a Q^{-1} power law in the regime $2L^{-1} \ll Q \ll r_C^{-1}$ and a Q^{-4} Porod power law for $Q \gg r_C^{-1}$. For near-infinitesimal r_C, $\mathrm{d}\Sigma/\mathrm{d}\Omega$ is given by

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V |\Delta\rho|^2 V_P \left[\frac{2S_i(QL)}{QL} - \frac{\sin^2(QL/2)}{(QL/2)^2}\right], \tag{5.8.21d}$$

where $S_i(QL) = \int_0^{QL} (\sin u/u)\,\mathrm{d}u$. In this case, there is again no Porod Q^{-4} scattering and the terminal slope $\simeq Q^{-1}$ for $Q \gg 2L^{-1}$, but there is a Guinier regime at low Q with ${R_G}^2 = L^2/12$.

(iv) *Gaussian coil morphology (common in polymer science)* (Debye, 1947). SAS (especially SANS) has been applied to a myriad of situations in polymer science. It is not possible here to include all of the form factors of interest, and these have been reviewed elsewhere (Pedersen, 2000). Nevertheless, we include one generic case, common in polymer science, which is that of a polymer Gaussian coil with mean radius of gyration R_G and mean volume V_P:

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V |\Delta\rho|^2 V_P \left\{ 2\frac{\left[\exp\left(-Q^2R_G^2\right) + Q^2R_G^2 - 1\right]}{Q^4R_G^4} \right\}. \tag{5.8.22}$$

In many practical polymer applications, it is convenient to re-write Φ_V and V_P in terms of the polymer molecular mass and density. It should be noted that for $QR_G \gg 1$, equation (5.8.22) predicts that $\mathrm{d}\Sigma/\mathrm{d}\Omega \simeq Q^{-2}$, similar to the power law found for the scattering from thin discs.

(v) *Core–shell particles* (Guinier & Fournet, 1955). Many SAS applications involve core–shell particles of one kind or another. These range from quantum-dot nanoparticles involving more than one component, through many systems where the scattering particles are coated with other organic or inorganic species, to the entire class of hollow particles (including micelles and vesicles). It is not feasible to cover all core–shell particle types here, but a generic example is given for guidance. Essentially, the SAS intensity for a core–shell particle is determined by considering it as an inner particle inside an outer particle. The form factor of the inner particle core with respect to the shell is summed coherently with the form factor of the outer particle with respect to the external medium. For a spherical core–shell particle of overall (shell) radius, $R_{\rm shell}$ and internal (core) radius, $R_{\rm core}$, with X-ray or neutron scattering-length densities $\rho_{\rm shell}$, $\rho_{\rm core}$ and ρ_O, respectively, for the shell, core and external (solvent) medium

$$\begin{aligned}\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} &= \\ \frac{\Phi_V}{V_P}&\left| \left\{ 3V_C(\rho_{\rm core} - \rho_{\rm shell}) \frac{\left[\sin(QR_{\rm core}) - QR_{\rm core}\cos(QR_{\rm core})\right]}{(QR_{\rm core})^3} \right\} \right. \\ &\left. + \left\{ 3V_P\left(\rho_{\rm shell} - \rho_O\right) \frac{\left[\sin(QR_{\rm shell}) - QR_{\rm shell}\cos(QR_{\rm shell})\right]}{(QR_{\rm shell})^3} \right\} \right|^2,\end{aligned} \tag{5.8.23}$$

where Φ_V is the volume fraction of the overall particles of volume $V_P = 4\pi R_{\rm shell}^3/3$, and $V_C = 4\pi R_{\rm core}^3/3$. Equation (5.8.23) can be re-written in terms of the core volume and core volume fraction, or the shell volume and shell volume fraction, by re-scaling Φ_V and V_P appropriately. While the equations become more complex, the same basic principle applies to the scattering intensity from other core–shell particle shapes. For a hollow particle where $\rho_{\rm core} = \rho_O$, the inner particle is essentially subtracted from the outer particle in the form-factor term before squaring. In such a case where the shell thickness $\tau_{\rm shell} \ll R_{\rm core}$ (and $R_{\rm shell}$), equation (5.8.23) gives Q^{-2} scattering in the regime $R_{\rm core}^{-1} \ll Q \ll \tau_{\rm shell}^{-1}$. Note that this is the third scenario discussed in this section where Q^{-2} scattering is observed. Prior knowledge is needed in such scenarios to determine which one applies.

The characteristic SAS intensity as a function of Q is illustrated for several of the above scenarios in Fig. 5.8.7. The scattering from randomly oriented, monodispersed scattering features is compared with that from polydispersed scattering features of the same shape, where the FWHM of the size distribution is ~20%.

5.8.3.1.6. *Particle pair density distribution function (PDDF)*

All of the particle shapes considered in Section 5.8.3.1.5 model the scattering intensity *versus* Q as a Fourier transform of the scattering-particle (or feature) morphology. An alternative approach is to use an indirect Fourier transform method to extract the real-space function that gives rise to the scattering intensity (Glatter, 1977). This can then be interpreted in terms of the disordered scattering-feature morphology that may be present in the sample. For circularly symmetric small-angle scattering around the incident-beam direction, the particle pair density distribution function, PDDF or $p(r)$, is given by

$$p(r) = \frac{1}{2\pi^2} \int\limits_0^\infty \frac{\mathrm{d}\Sigma(Q)}{\mathrm{d}\Omega} Qr \sin(Qr)\,\mathrm{d}Q. \tag{5.8.24a}$$

Meanwhile

$$\frac{\mathrm{d}\Sigma(Q)}{\mathrm{d}\Omega} = 4\pi \int\limits_0^\infty p(r) \frac{\sin(Qr)}{Qr}\,\mathrm{d}r. \tag{5.8.24b}$$

We note that $p(0) = 0$, but

$$\frac{\mathrm{d}\Sigma(0)}{\mathrm{d}\Omega} = 4\pi \int\limits_0^\infty p(r)\mathrm{d}r = \Phi_V |\Delta\rho|^2 V_P. \tag{5.8.24c}$$

The inverse transform of equation (5.8.24a) is indirect in the sense that it must be carried out using an iterative inversion technique. Comparing equation (5.8.24b) with equation (5.8.2a), we note that the particle PDDF (which has units of $\mathrm{m}^{-2}\,\mathrm{sr}^{-1}$) is related to the atomic pair correlation function by $p(r) = n_P |\Delta\rho|^2 V_P r^2 \gamma(r) = \Phi_V |\Delta\rho|^2 r^2 \gamma(r)$. Comparison with equation

(5.8.16) indicates that $\gamma(0) = 1 - \Phi_V$, or for a dilute system $\gamma(0) = 1$. Meanwhile, the mean radius of gyration (or Guinier radius), R_G, of any particulate features present is given by

$$R_G^2 = \frac{\int_0^\infty p(r) r^2 \,\mathrm{d}r}{2\int_0^\infty p(r)\,\mathrm{d}r}. \tag{5.8.25}$$

The main advantages of using the PDDF method in SAS studies are that the scattering morphology can be modelled directly in real space and that the $p(r)$ function is essentially model-independent, so its use is tractable for a wide range of applications and analysis. Potential disadvantages are that (as with the scattering invariant) it is not possible to measure over the entire Q range required by the integral in equation (5.8.24*a*), so data must be extrapolated; and that the PDDF is affected by, and contains information on, any dispersion in the scattering feature size or shape. Whether it is preferable to model these effects in $\mathrm{d}\Sigma/\mathrm{d}\Omega$ *versus* Q or $p(r)$ *versus* r depends on the details of the scattering system.

5.8.3.1.7. *Size distribution analysis*

In the general case, SAS arises from scattering features that are not monodispersed in either shape or size. Frequently, it is not possible to distinguish polydispersity in shape from that in size as the SAS intensity profile is sensitive to variations in the dimensions of the scattering objects, whether coming from size or shape variation. For example, the scattering from a finite-width size distribution of spheroidal scattering objects with either $\beta < 1$ or $\beta > 1$ is identical to that from a different (broader) size distribution of spherical ($\beta = 1$) objects. In most cases, the shape of the scattering features can be inferred from prior information, and so it is a size distribution of entities of a given shape that is sought from the scattering data. There are in general two ways of accomplishing this, and these are now described.

(i) *Model size distributions*. One approach to size distribution analysis is simply to fit a size distribution, $\varphi_S(R_O)$, of an assumed functional form and average the scattering over the size distribution. For example, in the case of spheroidal scattering features, equation (5.8.18) becomes

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = |\Delta\rho|^2 \int\limits_0^\infty \phi_V(R_O) V_P(R_O) \frac{9\pi}{2} \int\limits_0^1 \frac{[J_{3/2}(u)]^2}{u^3}\,\mathrm{d}X\,\mathrm{d}R_O, \tag{5.8.26}$$

where $V_P(R_O)$ is the volume of features of radius R_O. The advantage of fitting an assumed model size distribution is that various weighted-average sizes of interest can be extracted analytically from the result. To illustrate this, a lognormal size distribution can be assumed with minimum, mode, median and mean radii given by $R_{O\mathrm{min}}$, $R_{O\mathrm{mode}}$, $R_{O\mathrm{med}}$ and $R_{O\mathrm{mean}}$. If $A(R_O) = (R_O - R_{O\mathrm{min}})/(R_{O\mathrm{med}} - R_{O\mathrm{min}})$, $B_O = (R_{O\mathrm{med}} - R_{O\mathrm{min}})/(R_{O\mathrm{mode}} - R_{O\mathrm{min}})$, then

$$\phi_\mathrm{V}(R_O) = \frac{\Phi_V}{\{2\pi\ln(B_O)\}^{1/2}}\left(\frac{1}{R_O - R_{O\mathrm{min}}}\right)\exp\left\{\frac{-\{\ln[A(R_O)]\}^2}{2\ln(B_O)}\right\}, \tag{5.8.27}$$

and several useful parameters can be extracted from the size distribution analytically. For example: $R_{O\mathrm{mean}} = R_{O\mathrm{min}} + \{B_O{}^{1/2}(R_{O\mathrm{med}} - R_{O\mathrm{min}})\}$, the number-weighted mean radius, R_{ON}, is given by $R_{ON} = R_{O\mathrm{min}} + \{B_O{}^{-1/2}(R_{O\mathrm{mode}} - R_{O\mathrm{min}})\}$, and the surface area per unit sample volume of the distribution S_V, is given by $S_V = 3\Phi_V/R_{ON}$. Obviously, other model size distributions may be appropriate in given situations, and corresponding expressions can be used for these and similar ensemble averages. In general, a fitted model size distribution permits differences in a material system to be quantified as a function of differences in processing or other conditions, using a relatively small number of parameters.

(ii) *Size distributions using entropy maximization or other regularization.* An alternative approach to the least-squares fitting of a model function for the scattering-feature size distribution to the scattering data is to consider the contributions to the scattering intensity *versus* Q, from each histogram size bin within the size range of interest. In principle, the scattering contributions from each of the N size bins in a size distribution (assuming a given shape) can be treated as independent variables and fitted to the data by a least-squares method to determine the size distribution present. In practice, the large number of fitting parameters involved can make convergence to a unique solution, satisfying a good-fit χ^2 condition with respect to the measured data, difficult if not impossible. Furthermore, there is nothing to prevent unphysical negative regions from appearing in the fitted size distribution. Thus an additional constraint needs to be applied. Regularization methods link this second constraint to the minimum or required χ^2 condition *via* the use of a Lagrange multiplier. Two widely used additional constraints are either to require the size distribution to have maximum configurational entropy or to require that the size distribution is maximally smooth (free from oscillatory artifacts). In both cases, a major advantage is that the mathematical formulation is set up to ensure that the resulting size distribution is everywhere intrinsically positive.

The size distribution is assumed to extend over a finite scale range, associated with the SAS data, and to comprise a sufficiently large number of size intervals so as to capture the observable features in the size distribution. The size-interval increments are usually constant in linear size (relatively narrow population and a limited overall size range) or in logarithmic size (large dynamic range in the size of contributing features, and/or large range in the Q range investigated with constant $\Delta Q/Q$ resolution). Using similar notation as in previous sections, if $\varphi(R_i)$ is the value of the volume fraction distribution function for the ith size bin associated with size R_i (not necessarily R_O for a sphere or spheroid; any constant shape may be assumed), then the volume fraction in the ith size bin is $f_i = \varphi(R_i)\Delta R_i$ where ΔR_i is the width of the ith size bin. A configurational entropy, S_C, of the size distribution can then be defined in the convenient form

$$S_C = -\sum_{i=1}^{\mathrm{N}} \frac{f_i}{h}\log\left(\frac{f_i}{h}\right), \tag{5.8.28a}$$

where h is a baseline constant (or a default distribution, h_i), such that f_i/h is sufficiently large for Stirling's approximation to apply, *i.e.* $\log[(f_i/h)!] = (f_i/h)\log(f_i/h) - (f_i/h)$. (This is needed for all f_i of significance in the computing algorithm.) Note that the $\log(f_i/h)$ term implies that the f_i components are all positive. Entropy-maximization algorithms then find the histogram size distribution, f_i, hence the differential size distribution $\varphi(R_i)$, that meets the requirement

$$S_C - L_S\chi^2 = \text{a maximum}, \tag{5.8.28b}$$

where L_S is a Lagrange multiplier. Subject to the χ^2 requirement, analogous to the case in thermodynamics, the resulting maximum configurational entropy histogram distribution, f_i, is the most likely. However, because Bessel-function oscillations appear in the scattering from most assumed shapes for the scattering features, oscillations can still appear in the size distribution obtained, especially when this is a narrow distribution, despite applying the maximum entropy (*MaxEnt*) constraint (Potton *et al.*, 1988; Morrison *et al.*, 1992).

To find the smoothest size distribution consistent with the scattering data, it is necessary to define the roughness of the distribution, Z_C,

$$Z_C = \sum_{i=1}^{N} \left(f_{i+1} - f_i\right)^2 + f_1^2 + f_N^2, \qquad (5.8.29a)$$

and to satisfy the condition

$$Z_C + L_Z \chi^2 = \text{a minimum}, \qquad (5.8.29b)$$

where L_Z is another Lagrange multiplier.

Although frequently applied to obtain scattering-feature size distributions, this method, simply referred to as regularization in SAS analysis, was applied originally to optimize the PDDF $p(r)$ functions produced from SAS data *via* the indirect Fourier transform technique (Glatter, 1977, 1980). The maximum-entropy method has also been applied directly to derive PDDF $p(r)$ functions.

5.8.3.1.8. *Particle structure factor and interparticle interference effects*

With the exceptions of the scattering invariant and the Debye–Bueche approximation, our discussion so far has assumed that the SAS intensity arises from a dilute, disordered ensemble of discrete scattering features (particles or pores). In the terminology of equation (5.8.2*a*) this implies that the particle structure factor $S_P(Q)$ = 1. For many scattering morphologies, this assumption holds well for $\Phi_V < \sim 0.05$ (or 5%), although the effects of higher concentration are frequently neglected for $\Phi_V < \sim 0.10$. However, once the volume fraction of the scattering features is significantly above this, interparticle interference effects, as expressed in the particle structure factor $S_P(Q)$, can be significant. In general, it can be shown that (Guinier & Fournet, 1955)

$$S_P(Q) = 1 + n_P \int_0^{\infty} \left[g_P(r) - 1\right] \frac{4\pi r^2 \sin(Qr)}{Qr} \, \mathrm{d}r \qquad (5.8.30a)$$

and

$$g_P(r) = 1 + \frac{1}{2\pi^2 n_P} \int_0^{\infty} \left[S_P(Q) - 1\right] \frac{\sin(Qr)}{Qr} Q^2 \, \mathrm{d}Q, \qquad (5.8.30b)$$

where $g_P(r)$ is the dimensionless *particle* pair correlation function. Apart from the different normalization of equations (5.8.30*a*) and (5.8.30*b*) compared to equations (5.8.24*b*) and (5.8.24*a*), respectively, the slightly different form arises due to the exclusion volume around the centre of each scattering particle within which the centre of a neighbouring particle cannot approach. While this may not be strictly true for a population of voids or pores, it needs to be at least approximately true for a formalism assuming a concentrated population of discrete scattering features with well separated form-factor and structure-factor terms. It should also be noted that the actual radial distribution function for neighbouring particles, $Y_P(r)$, with units of m^{-1}, is given by $Y_P(r) = 4\pi r^2 n_P g_P(r)$.

In principle, equations (5.8.30*a*) and (5.8.30*b*) permit $g_P(r)$ and $Y_P(r)$ to be determined from an experimentally determined $S_P(Q)$, which in turn is extracted from $\mathrm{d}\Sigma/\mathrm{d}\Omega$ *versus* Q by dividing $\mathrm{d}\Sigma/\mathrm{d}\Omega$ by the known or assumed $n_P|\Delta\rho|^2 V_P^2 F_P^2(Q)$ or $\Phi_V |\Delta\rho|^2 V_P F_P^2(Q)$. The actual situation is complicated if any finite dispersion in the scattering feature size is present. The $S_P(Q)$ term in equation (5.8.2*a*) should then be replaced by $S_1(Q)$ where for a hard-sphere Percus–Yevick model (Percus & Yevick, 1958)

$$S_1(Q) = 1 + B_P(Q)\left[S_P(Q) - 1\right] \qquad (5.8.31a)$$

and

$$B_P(Q) = \left|\langle F_P(Q)\rangle\right|^2 \Big/ \left\langle \left|F_P(Q)\right|^2 \right\rangle. \qquad (5.8.31b)$$

Depending on how broad the size dispersion actually is, an interparticle interference may not be apparent in the scattering data. Nevertheless, the effects of high concentration [deviation of $S_P(Q)$ from 1] may still be significant.

5.8.3.1.9. *Fractal models*

Fractal scattering morphologies, despite generally being disordered in nature, are defined by their scale invariance and give rise to non-integral power laws in small-angle scattering. Examples of material systems incorporating fractal morphologies tractable for analysis by SAS methods abound, and include molecular sieves (Pauly *et al.*, 1999), dendrimers (Scherrenberg *et al.*, 1998), nanoparticle–polymer nanocomposites (Jouault *et al.*, 2009), aerogels (Emmerling & Fricke, 1992), crystallization phenomena (de Moor *et al.*, 1997), nanoparticle aggregates in flames (Hyeon-Lee *et al.*, 1998), Stober nanoparticle ensembles (Green *et al.*, 2003), cements and porous rocks (Allen, 1991), and asphaltene suspensions (Roux *et al.*, 2001). In some of these systems the solid phase, *e.g.* an assembly of nanoparticles, obviously forms the fractal morphology; in other systems, *e.g.* porous rocks, it may be the porous void network that constitutes the primary fractal morphology.

(i) *Mass- or volume-fractal morphologies.* In the case of a mass- or volume-fractal morphology, the mass and volume of the scattering features within a radius *r* of any one point in the morphology scales not with r^3, but with r^{D_V} where $D_V < 3$. The associated scattering power law can be shown to be Q^{-D_V}. For a contiguous scattering phase $D_V \geq 1$. $D_V = 1$ indicates a 1D chain structure and $D_V = 3$ indicates a space-filling phase with no fractal dependence. Thus $1 \leq D_V \leq 3$ for volume-fractal morphologies. However, $D_V = 2$ indicates a sheet-like structure, and $D_V < 2$ can be associated with a 2D fractal structure within an overall sheet-like morphology. So for three Euclidean dimensions $2 \leq D_V \leq 3$. Generally there is a maximum length scale, the correlation length ξ_V, over which volume-fractal scaling applies, and there is also a minimum length scale associated with the smallest scattering features that make up the fractal morphology. In the case of solid features of radius R_O, the minimum possible dimension for fractal scaling is the correlation hole radius, $R_C = 2R_O$, the minimum separation distance for centres of neighbouring particles. With a local packing fraction of η assumed within the correlation hole radius, and approximating the normalization to give extrapolation to Q = 0 consistent with a

Guinier approximation for the fractal structure (Freltoft *et al.*, 1986),

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \Phi_V|\Delta\rho|^2 V_P\left[\frac{\eta R_C^3}{R_O^3}\left(\frac{\xi_V}{R_C}\right)^{D_V} \times \left(\frac{\sin\left[\left(D_V-1\right)\arctan\left(Q\xi_V\right)\right]}{\left[1+(Q\xi)^2\right]^{\left(D_V-1\right)/2}\left(D_V-1\right)Q\xi_V}\right) + (1-\eta)^2\right]F^2(Q), \tag{5.8.32}$$

where Φ_V is the total volume fraction of the scattering features, here assumed to be spheres of volume $V_P = 4\pi R_O^3/3$ with scattering form factor $F^2(Q)$ that comprise the volume-fractal microstructure. The trigonometric terms refer to angles in radians and the arctangent angle is in the principal range from zero to $\pi/2$. This expression exhibits Q^{-D_V} scattering in the Q range $\xi_V^{-1} \ll Q \ll R_O^{-1}$, single-particle form-factor scattering in the range $Q \geq R_O^{-1}$ (including Porod Q^{-4} scattering for $Q \gg R_O^{-1}$), and the scattering Q-dependence 'tops out' for $Q \leq \xi_V^{-1}$. Volume-fractal SAS data can be fitted using this function with Φ_V, R_O, D_V, ξ_V and η as fitted parameters (plus a flat background term if needed). However, it must be emphasized that this can only be done if the data can be measured over a sufficient Q range and with sufficient Q resolution for the different scattering regimes indicated to be apparent in the data. If this condition is not met, other prior knowledge must be used to constrain the fitting parameters. Otherwise, equation (5.8.32) cannot result in convergence to a unique solution. This is particularly the case when other morphology components are present, such as surface-fractal scattering.

(ii) *Surface-fractal morphology*. Any rough interface between two phases exhibits the property that its measured surface area increases when additional roughness at finer length scales is included. Surface-fractal roughness occurs when a fixed exponent links the surface-area value to the inverse of the roughness scale considered. A true surface fractal involves roughness in all three dimensions with a convoluted surface topology that includes re-entry (doughnut-like) geometries. However, when the chord length across strands of the structure is comparable with the roughness scale being considered (Q^{-1}), SAS 'sees' this as a 3D structure, not as a rough 2D interface. For SAS applications, surface-fractal morphology is limited to an interface with self-affine 2D roughness that, otherwise, can be considered essentially planar in nature. Within this limitation, a surface fractal occurs when the number of surface elements of area $\Delta S(r)$ needed to cover an interface with roughness included down to a length scale r scales as r^{-D_S} where $D_S \geq 2$. We note that a smooth interface has $D_S = 2$. Once again, we assume that there is a maximum length scale or correlation length, ξ_S, over which the fractal roughness occurs, usually related to the size of the (large) features that possess the interface with fractal surface roughness. Generally, ξ_S can be associated with the geometrically smooth surface area, S_O. With these terms defined, a full expression for surface-fractal scattering can be derived using a generalization of Porod's law (Bale & Schmidt, 1984):

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}\Omega} = \frac{\pi\xi_S^4|\Delta\rho|^2 S_O\Gamma\left(5-D_S\right)\sin\left[\left(3-D_S\right)\arctan\left(Q\xi_S\right)\right]}{\left[1+\left(Q\xi_S\right)^2\right]^{\left(5-D_S\right)/2} Q\xi_S}, \tag{5.8.33}$$

where $\Gamma(5 - D_S)$ refers to the Gamma function. When $D_S = 2$, equation (5.8.33) reduces to the Porod expression of equation (5.8.15). For a self-affine surface-fractal interface $2 \leq D_S \leq 3$, and the expression exhibits a $Q^{-(6-D_S)}$ power law for $Q \gg \xi_S^{-1}$. Again the scattering intensity 'tops out' for $Q \leq \xi_S^{-1}$. Unlike the approximate normalization at low Q provided by equation (5.8.32) for a volume-fractal morphology, the normalization at low Q provided by equation (5.8.33) for a self-affine surface-fractal morphology is exact. Equation (5.8.33) can be used fit to experimental data using three parameters: S_O, D_S and ξ_S. A further term like that used in equation (5.8.32) can be introduced to deal with the scattering at high Q. Alternatively, some other morphology such as volume-fractal scattering (power law between Q^{-2} and Q^{-3}) may take over from the steeply declining surface-fractal scattering (power law between Q^{-3} and Q^{-4}), and it may not be necessary to truncate the surface-fractal scattering at high Q. For a minimum roughness scale, R_O, where surface-fractal scaling applies, the fully rough surface area, S_{SF}, is related to the geometrically smooth surface area, S_O, by $S_{\mathrm{SF}} = S_O(\xi_S/R_O)^{(D_S-2)}$.

Particularly if volume- and surface-fractal morphologies coexist, it is essential that SAS data cover sufficient Q range (*e.g.*, $\xi_V^{-1} < Q < R_C^{-1}$ for a volume fractal) with sufficient Q resolution, and that sufficient parameter constraints based on prior knowledge be applied, to achieve convergence to a unique solution. In practice, fractal microstructures being hierarchical in nature, SAS data over three to four decades in Q, and perhaps eight or nine decades in intensity, are required. Despite these conditions, once an acceptable model paradigm is implemented, fractal models offer the advantage of combining single-feature scattering, dispersion effects and concentrated morphology issues into a single approach for fractal disordered systems.

In this and previous sections, we have considered physical microstructure models that produce the scattering observed. How well any one physical model can fit the data depends, at least to some extent, on how well the microstructure assumed approximates to that actually present. Unfortunately, while misfits should occur if the wrong model is assumed, they can also occur if the correct basic model is assumed but the actual situation is less idealized than the model implies, or if the data-point density and weighting *versus* Q make fitting of the SAS profile function mathematically ill-conditioned. One approach to addressing this situation is to develop a hierarchical nest of numerical fitting functions for SAS data that can achieve good and stable fits over a large Q range and for many situations. Having obtained a good fit, the SAS interpretation problem is then transferred to developing a credible physical interpretation of the mathematical fit parameters obtained. An obvious disadvantage is that the mathematical parameters can be misinterpreted. Nevertheless, one such approach that has met with considerable success in recent years, especially in the analysis of SAS data from polymer systems, is the 'unified fit' model developed by Beaucage (1995).

5.8.3.1.10. *Anomalous SAXS and contrast-variation SANS*

Intrinsic wide-angle and small-angle scattering intensities arise from the X-ray atomic scattering form factors, or the neutron nuclear scattering lengths (*i.e.*, b_i, b_j) for the various atomic species within a material. In diffraction, these are manifested in summations such as given in equation (5.8.6). In SAXS or SANS, the scattering contrast factors, $|\Delta\rho|^2$, derived from the scattering-length densities, determine the intrinsic strength of the scattering, as indicated in equation (5.8.2*a*). In many materials that are partially disordered and/or heterogeneous, several measurements involving both X-rays and neutrons may be desirable to determine the compositions, densities and phases of the components giving rise to the scattering. However, in both X-ray and neutron measurements, it is possible to vary the scattering lengths and contrast factors in order to interrogate the various scattering components within a single set of measurements. For WAXS and SAXS, this can be done at an X-ray synchrotron by varying the X-ray energy just below the absorption-edge energy for an atomic species present in a material of interest. For WANS and SANS, the neutron isotope effect is exploited by varying the isotope mix of one of the constituents present in the sample material, *e.g.*, H_2O/D_2O contrast variation. While these effects can be exploited in both diffraction and small-angle scattering, here we concentrate on SAXS and SANS.

(i) *Anomalous SAXS*. Just below the X-ray energy for resonant absorption by an atom of a given element (a characteristic absorption edge, obtainable from published tables, but also measurable at synchrotron sources by careful tuning of the X-ray energy using calibration absorption foils), the X-ray form factor, b_i, deviates significantly from its normal (non-resonant) value measured at X-ray energies far from an absorption edge (Thompson, 2009). Consequently, the X-ray scattering contrast factor $|\Delta\rho|^2$ applicable to SAXS measurements of any heterogeneous scattering features incorporating the given element also varies (anomalously) with the X-ray energy. Fundamental derivations of resonant-scattering contrast factors and their formal incorporation into the interpretation of anomalous SAXS (ASAXS) measurements are described in detail elsewhere (Cromer & Liberman, 1970; Hoyt *et al.*, 1984). For the purpose of ASAXS measurements of heterogeneities in disordered materials, it suffices to apply the following approximate relationship between the energy-dependent SAXS contrast factor, $|\Delta\rho(E)|^2$, and the X-ray energy, E, when this is below the absorption energy, E_0, by a few tens of eV:

$$\left|\Delta\rho(E)\right|^2 = |\Delta\rho|^2_{NR} + A_{E_0} \ln\left(\frac{E_0 - E}{E_0}\right), \qquad (5.8.34)$$

where $|\Delta\rho|^2_{NR}$ is the scattering contrast factor at X-ray energies far from the absorption edge and A_{E_0} is a scattering contrast constant for the specific material and absorption energy of interest. Note that the $\ln[(E_0 - E)/E_0]$ factor is strongly negative and ASAXS measurements must be made at $E < E_0$ because of the large decrease in sample transmission for $E > E_0$ as a result of the large increase in resonant X-ray absorption by the sample at $E = E_0$. While $|\Delta\rho|^2_{NR}$ is always positive, A_{E_0} is positive when the electron density is higher in the phase containing the element associated with the X-ray absorption edge, resulting in a decrease in scattering contrast with X-ray energy as the absorption-edge energy E_0 is approached from below. However, A_{E_0} is negative when the electron density is lower in the phase containing the X-ray-absorption-edge element, resulting in an increase in scattering contrast with X-ray energy as the absorption edge is approached from below. While ASAXS contrast variation with energy can be subtle, its careful measurement close to appropriate X-ray absorption edges can provide important insights into the composition and density of heterogeneities in disordered materials (Allen *et al.*, 2014).

(ii) *Contrast-variation SANS*. The strong isotope effect in neutron scattering lengths (Sears, 1992), together with the sensitivity of neutrons to hydrogen in hydrogenous materials, which are frequently disordered, makes these materials prime targets for investigation by contrast-variation SANS. Taking H_2O/D_2O contrast variation as an example, the neutron scattering-length density of H_2O is given by $\rho_H = -0.56 \times 10^{14}\,m^{-2}$, while for D_2O $\rho_D = +6.40 \times 10^{14}\,m^{-2}$. Since H_2O, HDO and D_2O are completely mixable at the atomic level, the scattering-length density of an H_2O/D_2O mix can be interpolated between these two end points for any molar mix of H_2O and D_2O. Furthermore, most solid hydrogenous materials have scattering-length densities between ρ_H and ρ_D. Thus, if the SANS is measured for a series of porous samples containing various H_2O/D_2O mixes in the pore water, the absolute-calibrated SANS intensity profile of $d\Sigma/d\Omega$ *versus* Q should remain the same as a function of D/H ratio, except that the absolute intensity across the Q range will follow a parabola in $|\Delta\rho|^2$, going to zero at the contrast match point where the scattering-length density in the pore water matches that of the solid phase. For a genuine two-phase system (one solid phase plus the pore fluid), the contrast match point can be found by plotting the square root of the intensity *versus* the molar fraction of D_2O, with negative values on the H_2O side of the estimated match point and positive values on the D_2O side. A straight-line fit then gives the match point as the intercept on the horizontal axis.

The situation is more complicated when more than one solid phase is present, as each solid phase has its own contrast-variation parabola with the pore fluid. The weighted sum of these parabolas is still a parabola, but now there is a contrast minimum with finite residual intensity (no one phase matched) at the minimum. If some of the solid phases have known composition and density, it may be possible to subtract these out, leaving a contrast-match curve for an unknown phase. Another complication occurs when the H_2O/D_2O exchange does not occur uniformly at all length scales. A decision must then be made as to which scale (and hence Q) to apply the contrast-variation analysis to. It is also possible to apply contrast-variation analysis to hydrogenous systems formed using various H/D isotope mixes, but care must be taken to ensure that the H/D exchange does not affect the reaction times which, despite the chemical equivalence of the hydrated and deuterated components, is not always the case. Despite these issues, SANS contrast-variation measurements play an important role in the investigation of heterogeneous and disordered materials, especially where a lack of crystallinity in one or more critical phases precludes many other diffraction-based analyses, as in the case of polymers or cements (Allen *et al.*, 2007).

5.8.3.1.11. *Magnetic SANS analysis*

As mentioned earlier in Section 5.8.2, neutrons, having a magnetic moment themselves, interact with atoms that also have a net magnetic moment. Much of what we know about magnetism or magnetic phenomena within materials has been discovered through magnetic neutron scattering and diffraction, *e.g.*, Ritter *et al.* (1997) (see also Chapter 2.8). Here, we add brief comments mainly regarding magnetic SANS analysis of heterogeneous magnetic materials. Even in a material containing atoms or molecules possessing net magnetic moments, there is no magnetic

SANS intensity if these magnetic moments are randomly oriented (although there may be a contribution to the incoherent flat background scattering). However, if magnetic ordering is present (ferromagnetic, antiferromagnetic, ferrimagnetic *etc.*), and if an axis of magnetic alignment is established, *e.g.* by applying a saturation magnetic field to align the atomic magnetic moments (or those of any magnetic domains present), an anisotropic magnetic SANS contribution can be measured. The magnetic SANS intensity varies as $\sin^2\alpha$, where α is the angle between the direction of the neutron magnetic moment and that of the sample (*i.e.*, that of the applied magnetic field). Analysis of the anisotropic intensity collected using a 2D PSD allows the anisotropic ($\sin^2\alpha$) magnetic SANS component to be separated from the (usually isotropic) nuclear SANS component.

Once the anisotropic nature of the magnetic SANS data is allowed for, the full set of analyses discussed previously in Section 5.8.3 can be applied, using the magnetic SANS contrast factors in place of the non-magnetic contrast factors, to model and quantify magnetic microstructures and heterogeneities that are present. Significant magnetic SANS studies have included precipitation phenomena in ferritic steels (Allen *et al.*, 1993; Mathon *et al.*, 2003), the magnetic structure of nanocrystalline iron (Wagner *et al.*, 1991), polarons in perovskites (De Teresa *et al.*, 1997) and flux-line lattice behaviour in superconductors (Yaron *et al.*, 1995; Riseman *et al.*, 1998). Magnetic SANS investigations have been made even more powerful by the development of polarized SANS instrumentation (SANSPOL) that uses supermirrors to provide significant polarization of the incident neutron beam (Zhao *et al.*, 1995). The spin-dependent scattering of polarized neutrons enables models for heterogeneous magnetic structures to be more finely tuned, as well as providing a better separation of the magnetic and non-magnetic scattering components in the experimental data (Heinemann & Wiedenmann, 2003; Mettus & Michels, 2015).

Finally, it should be mentioned that neutron-polarization analysis has been extended well beyond the magnetic SANS regime. Following the development of the neutron spin-echo technique by Mezei and others in the 1970s (Mezei, 1980), spin-echo SANS (SESANS) instruments have been designed to compare the neutron polarization before and after the sample position, and measure changes in the Larmor precession angle of the neutron polarization plane as neutrons traverse a sample. Although the analysis can be complex and goes beyond the scope of this chapter, this technique, which is applicable to all classes of sample systems, not just magnetic samples, can provide unique information on the dynamics of an ensemble system (including biological systems), as well as structural information over a length scale that overlaps with USANS (Rekveldt, 1996).

5.8.3.1.12. *Further analysis of X-ray reflectivity and GI-SAXS*

Some further discussion is warranted of disorder that can occur at surfaces and interfaces in materials, or within thin films:

(i) *Parratt function reflectivity profile* (Parratt, 1954). Assuming specular reflectivity $R(Q)$ *versus* Q data have been obtained and corrected as discussed previously, these can be analysed to give a density profile of a series of N thin-film layers on a substrate, together with a representation of the roughness/diffuseness associated with each film boundary. Assuming a scattering-length density $\rho(z)$ as a function of overall distance z below the mean position of the top surface of the whole sample,

$$\rho(z) = \rho_O + \sum_{m=1}^{N+1} \frac{(\rho_m - \rho_{m-1})}{2}\left[1 + \operatorname{erf}\left(\frac{z - z_m}{\sigma_m\sqrt{2}}\right)\right], \tag{5.8.35}$$

where $z_m = \sum_{k=1}^{m-1}\tau_k$, ρ_O is the scattering-length density above the top film layer (frequently $\rho_O = 0$ unless the film interfaces are buried in some other bulk material or are immersed in a liquid), ρ_m is the scattering-length density in the mth film layer, $\operatorname{erf}(x)$ is the error function, σ_m is the standard deviation of the roughness (or diffuseness) for the mth interface at the top of the mth film (where the first interface at $z_1 = 0$ defines the top of the whole assembly), and z_m is the mean location of the mth interface and is the sum of the thicknesses, τ_k, of each film above the mth interface and film. Note that the final $(N + 1)$th interface is with the substrate and z_{N+1} is the combined thickness of all of the films.

Practical refinement of the density profile by fitting the predicted reflectivity curve to experimental reflectivity data must take into account corrections not only for overall sample geometry but also for instrumental resolution corrections *etc.* However, the reflectivity curve $R(Q)$ for a series of thin films on a substrate, as described above, can in principle be compared to the Fresnel reflectivity curve, $R_F(Q)$, from a perfectly smooth, bare substrate of scattering-length density ρ_{N+1}, here denoted $\rho_{\rm SUB}$, by (Als-Nielsen, 2001)

$$\frac{R(Q)}{R_F(Q)} = \left|\frac{1}{\rho_{\rm SUB}}\int\limits_{-\infty}^{\infty}\exp(iQz)\left(\frac{{\rm d}\rho}{{\rm d}z}\right){\rm d}z\right|^2, \tag{5.8.36}$$

where the integral range must be extended out in both directions until $\mathrm{d}\rho/\mathrm{d}z = 0$.

Note that specular reflectivity studies can detect a rough or diffuse boundary between successive films, but cannot themselves differentiate between the two. This said, neutron contrast-variation methods may sometimes be used to interrogate the composition at an interface (Nelson, 2006). However, in most cases, non-specular reflectivity or GI-SAXS measurements must be used to investigate the nature of the disorder occurring at the film interfaces (or within films), or to characterize in-plane structures parallel to the substrate.

(ii) *Distorted-wave Born approximation (DWBA)*. In Section 5.8.2.4 the case of GI-SAXS or NS-SANS from a microstructure within a single thick film was discussed and the various refraction corrections considered. However, in the more general case of thin films where $\zeta_{\rm mean} \geq \tau_{\rm film}$, at least four different contributions to the scattering must be considered: (i) a single scattering event as discussed in Section 5.8.2.4; (ii) a single scattering event, followed by reflection from the film/substrate interface; (iii) reflection from the film/substrate interface, followed by a single scattering event; and (iv) as (iii) but with a further reflection from the film/substrate interface and possibly a further scattering event. To some extent component (i) can be separated from (ii) to (iv), corrected for refraction effects and interpreted using the Born approximation. However, for a full treatment of GI-SAXS data from thin films where components (ii) to (iv) cannot be ignored, distortions from the incident plane wave assumed in the Born approximation must be allowed for in what is effectively a superposition of the four components – hence, the use of the DWBA (Sinha *et al.*, 1988; Rauscher *et al.*, 1995). Because of this, the DWBA does not simply provide a modified form of $d\Sigma/d\Omega$ that takes into account all of the corrections involved, but it also modifies the form factors and structure factors associated with the underlying microstructural features within a film.

It is not practical to give a full exposition of the DWBA in the context of this chapter. Fortunately, it can be shown that the DWBA only has a significant effect for incidence and scattering grazing angles, θ_i and θ_2, close to the critical angle θ_C. Furthermore, software tools are now publicly available that address the analysis needs for most of the main cases of interest. We refer the interested reader to the various references and software available: Lazzari (2002), Babonneau (2010) and Korolkov *et al.* (2012), the last of which is focused on GI-SANS.

5.8.3.2. *Small-angle scattering effects on wide-angle scattering analysis*

In Section 5.8.2.5, it was pointed out that the determination of the real-space atomic pair density distribution function, $G(r)$, from wide-angle scattering (diffraction) is affected by the non-measurable scattering contribution close to $Q = 0$. For a macroscopic diffracting sample volume, the missing scattering is effectively at infinitesimal Q, and its absence from the Fourier transform integral of equation (5.8.10) results in the negative term $-4\pi r n_0$ appearing in the expression for $G(r)$. We now consider the case where the diffracting regions giving rise to the wide-angle scattering (whether internally crystalline or atomically disordered) are, themselves, randomly distributed particles of nanoscale size within a solid matrix or liquid medium. The finite size of the particles now contributes measurable small-angle scattering at low Q. If this is not measured, a more complex negative term appears in the expression for $G(r)$ determined from a Fourier transform of the total-scattering data measured in the wide-angle regime.

In general it can be shown that equation (5.8.13) for the atomic pair density distribution function, $G(r)$, can be modified to become (Cargill, 1971; Farrow & Billinge, 2009)

$$G(r) = 4\pi r\big[n(r) - \gamma_0(r)n_0\big], \qquad (5.8.37)$$

where $n(r)$ is the atomic number density distribution at all r with respect to any given atom, n_0 is the mean atomic number density and $\gamma_0(r)$ is the dimensionless atomic pair correlation function of equations (5.8.2*a*,*b*). While $\gamma_0(r)$ can be determined empirically from calibrated SAXS or SANS data, it can also be defined in terms of an individual small-angle scattering particle (Porod, 1951; Guinier & Fournet, 1955; Glatter & Kratky, 1982). Let $c(\mathbf{r})$ be a shape function with the property that $c(\mathbf{r}) = 1$ for $\mathbf{r}$ inside the particle and $c(\mathbf{r}) = 0$ for $\mathbf{r}$ outside the particle. Then for any given particle orientation

$$\gamma_0(\mathbf{r}) = \frac{1}{V_P}\int_0^\infty c(\mathbf{r})c(\mathbf{r}+\mathbf{r}')\,d\mathbf{r}' \text{ and } \int_0^\infty \gamma_0(\mathbf{r})\,d\mathbf{r} = V_P, \qquad (5.8.38)$$

where for randomly oriented particles, such as would give an isotropic microstructure, the orientational average of $\gamma_0(\mathbf{r})$ is $\gamma_0(r)$. For nanoscale small-angle scattering particles, we note that $\gamma_0(r) = 0$ for r greater than the largest chord dimension of the scattering particle. This gives the characteristic shape of the $G(r)$ component shown in Fig. 5.8.6(*c*) when scattering in the SAS regime ($Q < Q_{\min}$) is not measured in total-scattering measurements. However, when the total scattering is measured for a very dilute ensemble of nanoparticles, the $G(r)$ function itself becomes featureless for r greater than the largest chord length of the scattering particles, as has been demonstrated experimentally (Proffen & Kim, 2009). Meanwhile, we also note that when r is very much less than the maximum chord dimension of the particles, such as is always the case when the particles are macroscopic in size, $\gamma_0(r) = 1$ and equation (5.8.37) reverts to equation (5.8.13).

5.8.3.3. *Combining information from different methods*

Increasingly, several diffraction-based techniques are being used together to interrogate disordered or partially disordered material systems. A major example offered here is the combination of SAXS or SANS at low Q with diffraction-based total-scattering methods at larger Q, or wide-angle scattering. In order to account fully for the SAS contribution in total-scattering data, or simply to combine diffraction and SAS data, it is necessary to inter-calibrate the scattered and diffracted intensities between the techniques. In this connection, it is important to allow for the different conventions in normalizing the scattered or diffracted intensities.

In SAXS or SANS, the macroscopic differential scattering cross section, $d\Sigma/d\Omega$, is used to give the normalized intensity, as defined in Section 5.8.2. In diffraction, the coherent diffraction intensity, $I_{\rm coh}$, is used as defined in equation (5.8.6), with $I_{\rm coh}$ derived from a coherent sum of the diffraction amplitudes from all of the diffracting atoms sampled. In equation (5.8.6) it is assumed that the scattering is normalized to an incident beam comprising a plane wave of unit amplitude (hence unit intensity), and that the individual contributions to the scattered wave are also normalized per unit solid angle. Thus, the additional normalization required to convert $I_{\rm coh}$ to $d\Sigma/d\Omega$ is with respect to the sample volume and $d\Sigma/d\Omega = I_{\rm coh}/V_S$. However, whereas the SAS expressions are based on the assumption that the SAXS or SANS intensity is small compared with the incident-beam intensity, this assumption does not necessarily hold for WAXS or WANS.

In practice, the quantitative comparison of SAXS and SANS intensities with those of WAXS and WANS can be complicated by a number of factors. Crystalline structure factors summed over significant coherently diffracting sample volumes can lead to extinction effects that affect the Bragg diffraction peak intensities. Similarly, the peak intensities can also be affected by crystalline texture, or by the presence of stress and strain. All these issues are discussed in Chapters 5.2 and 5.3, but they are less likely to have a significant effect for a partially disordered material having weak diffraction peaks, which is of most interest here. Two effects that do influence any quantitative comparison of the small- and wide-angle scattering from disordered materials are those due to thermal diffuse scattering (WAXS, WANS, total scattering) and multiple scattering (SAXS and SANS).

Thermal diffuse scattering (TDS) reduces the intensity of the diffraction peaks measured in WAXS or WANS and redistributes it to the background scattering between the peaks. The functional form of the latter depends on the details of the material in question, and this can be further complicated in the case of disordered or partially disordered materials in the context of total-scattering measurements. However, the reduction in coherent Bragg peak intensity and its effect on the determination of $G(r)$ can be treated by a modification of equation (5.8.8) to allow for the effect of the Debye–Waller factor (Farrow & Billinge, 2009):

$$S(Q)-1=\left(\frac{1}{N\langle b\rangle^2}\right)\sum_{i\neq j} b_j^* b_i\left[\frac{\sin(Qr_{ij})}{Qr_{ij}}\right]\exp\left(-\frac{\sigma_{ij}^2 Q^2}{2}\right), \tag{5.8.39}$$

where σ_{ij}^2 is the correlated Debye–Waller broadening factor (in real space) for the *i–j*th atom pair. The σ_{ij}^2 term includes the expected Arrhenius dependence on the absolute temperature, T.

Multiple scattering in SAXS or SANS reduces the scattering intensity at the lowest Q values measured and redistributes the lost intensity to higher Q values. However, without correction, this effect can be masked by an incorrect sample transmission T_S, used in place of T_{SS}, in equation (5.8.4) for the intensity calibration. The multiple-scattering correction outlined in Section 5.8.2.3.3 must be applied before combining SAXS or SANS data with WAXS or WANS. Obviously, it is necessary to integrate the scattering intensity out to a Q value beyond which multiple scattering can be ignored. (A decrease in apparent intensity of one decade from that at $Q = 0$ suffices in most cases.) As indicated previously, this correction, alone, does *not* correct for the distortion in the SAS profile at low Q where multiple scattering is significant, but it *does* correct the calibrated $\mathrm{d}\Sigma/\mathrm{d}\Omega$ for all higher Q values. Multiple-scattering corrections that include correcting some of the distortions in the SAS profile at low Q have been treated by Schelten & Schmatz (1980).

Assuming that corrected absolute scattering intensities can be attained, there are strong advantages in comparing these for WAXS and WANS, SAXS and SANS across corresponding Q ranges for partially disordered systems, especially where spatial variations in composition exist. To achieve this, the X-ray and neutron measurements need to be made on samples that are as closely identical to each other as possible, although the sample thickness and volume for neutrons must frequently be larger than for X-rays. A ratio of the WAXS/WANS integrated diffraction peak intensities for corresponding Bragg peaks provides a test of the diffracting unit cell composition of the crystalline component of a partially disordered material. This is because the values of the b_i and b_j for different atoms in the corresponding summations of equation (5.8.6) for X-rays and neutrons are different, allowing the predicted structural composition of a crystalline phase to be tested against experiment. Meanwhile, the ratio of the calibrated SAXS/SANS intensities over corresponding Q ranges provides a similar test of the overall composition and density of heterogeneities within the microstructure, regardless of whether the solid phase is crystalline or amorphous. Again, this is because the contrast factor $|\Delta\rho|^2$ in equation (5.8.2*a*) is different for X-rays and neutrons (Thompson, 2009; Sears, 1992), depending on the composition and density both of the small-angle scattering heterogeneities and of the surrounding medium. The proportionality between the X-ray form factor and atomic number for X-ray scattering *versus* the strong isotope effect for neutron scattering can lead to very different sensitivities of X-rays and neutrons to different components in a disordered heterogeneous material system. This is particularly true when disordered hydrogeneous species are present, some bound into the solid matrix, not all of which is crystalline. Clearly, the use of H/D contrast methods in WANS and SANS discussed in Section 5.8.3.1.10 can be strongly complemented by a comparison between the X-ray and neutron intensities.

Finally, we note the importance of relating the WAXS and SAXS and/or WANS and SANS results. In previous sections, we have shown the importance of accounting for the small-angle scattering in total-scattering measurements of partially disordered material systems. With the added complications of needing to treat thermal diffuse scattering and other defect-related corrections to the scattering observed, the advantages of working independently with both the X-ray scattering form factors and contrast factors, and the corresponding neutron scattering-length densities and contrast factors, are that the entire interpretation scheme can be independently checked using two sets of scattering parameters. Again we emphasize the value of such an approach when hydrogenous components are present in a partially disordered heterogeneous material system.

5.8.4. Prospects for future development and recommended further reading

At the present time, rapid advances are taking place in the diffraction- and scattering-based analysis of partially disordered and heterogeneous materials. What follows is a very brief summary of some of the more promising current developments.

5.8.4.1. *Developments at X-ray synchrotron facilities*

New third-generation X-ray synchrotron facilities continue to come on line to serve the full range of diffraction- and spectroscopy-based techniques for investigating phenomena in new materials. Among these is the application of increasingly ambitious instrumentation using high X-ray energies for total-scattering analysis of nanocrystalline and disordered or partially crystalline materials over a large Q range (Petkov *et al.*, 2013). Instrumentation has also been developed to combine methods such as USAXS, SAXS and WAXS (including atomic pair density distribution analysis) to provide both microstructure and structure data for given samples within a single set of measurements (Becker *et al.*, 2010). Where possible, the X-ray energy range is being extended to higher energies to allow investigation of thicker or denser, more complex materials (Ilavsky *et al.*, 2012). At the same time, the increasingly higher X-ray fluxes available are allowing better time resolution and the more direct *in situ* studies of complex processes involving disordered materials. These instrumental developments include both bulk sample measurements using transmission geometry, and surface and thin-film measurements using a reflection geometry. As the need has increased for *in situ* studies of processes occurring within material systems, rather than just structural and microstructural measurements of materials under static conditions, so has interest in combining methods such as SAXS with techniques such as X-ray photon correlation spectroscopy (XPCS) to measure the equilibrium and non-equilibrium dynamics of phenomena occurring within materials (Zhang *et al.*, 2011). In this connection, the recent development of X-ray free-electron laser (FEL) coherent scattering (LCS) or fourth-generation X-ray sources is likely to play a major role in the future (Saldin *et al.*, 2011), as will the ongoing development of multi-bend achromat (MBA) diffraction-limited storage rings at synchrotrons (Tavares *et al.*, 2014). The coherent aspects of these new X-ray sources will affect all areas of X-ray scattering and diffraction. Specifically, the new sources will spur a much greater integration of structure and dynamics considerations for all classes of material, including disordered and heterogeneous materials.

For current information on and links to major X-ray facilities and instrumentation around the world please see http://www.lightsources.org/regions.

5.8.4.2. *Developments at steady-state and pulsed neutron sources*

While neutron fluxes are never likely to match those possible with X-rays, the high penetration ability in most materials, the absence of sample beam damage and the strong isotope effect for neutron scattering present major advantages for studies of disordered and heterogeneous materials. The magnetic properties of neutrons, and also their sensitivity to inelastic processes in materials, also provide important advantages. As pulsed (spallation) neutron sources have been developed around the world in recent years, the field of neutron powder diffraction has advanced significantly (Ibberson, 2009; Garlea *et al.*, 2010). The availability of long-pulse operations at an increasing number of locations together with the construction of long-flight-path instruments have enabled major advances in neutron total-scattering measurements and, to some degree, combination of WANS with SANS within the same instrument configuration (White *et al.*, 2010; Bowron *et al.*, 2010). Meanwhile, at steady-state (reactor-based) neutron sources, the greater availability of cold neutrons and the ability to achieve higher signal-to-noise ratios for SANS continue to make reactors the prime location for dedicated SANS measurement. Recent innovations in neutron optics such as neutron refractive lenses, new detector developments and the development of successful USANS instruments are resulting in new emerging SANS capabilities, such as the ability to measure in several instrument configurations at once (Frielinghaus *et al.*, 2009; Huang *et al.*, 2012). This will greatly reduce sample measurement times and improve the time resolution for *in situ* studies of material processes. Indeed, reactor-based SANS measurements continue to lead the exploration of *in situ* processes in polymer systems and other disordered materials (Eberle & Porcar, 2012).

For current information on and links to major steady-state reactor and pulsed source neutron facilities and instrumentation around the world please see http://www.neutron.anl.gov/facilities.html.

5.8.4.3. *Future prospects*

In closing we note that advanced technological materials development is increasingly concerned with harnessing complex phenomena in multi-component and heterogeneous material systems. The materials involved are frequently a hybrid mix of alloys, polymers and ceramics, intimately connected for the intended purpose of the overall system. Many of the material components are nanoscale and/or nanocrystalline in nature, or have poor crystallinity, or none. Even if not disordered with regard to crystalline structure, disordered distributions of heterogeneous elements are frequently present, and they may even govern performance. While many of the techniques and practices described elsewhere in this volume are appropriate for providing the needed characterization of new material systems, we have attempted in this chapter to focus on suitable methods for characterizing and measuring their more disordered aspects.

6.1. Survey of computer programs for powder diffraction

C. J. Gilmore, J. A. Kaduk and H. Schenk

Table 6.1.1 lists currently available software for use in all areas of powder diffraction. It is based on the software database on the SINCRIS Information Server at http://www.cristal.org/DU-SDPD/nexus/iucr2/sincris-/index.htm supplemented by program references in chapters in this book and work carried out by Lachlan Cranswick before his untimely death. The latter can be found in Cranswick (2008) and on the CCP14 website at http://www.ccp14.ac.uk. CCP14 is curated in a minimal way by Professor Jeremy Cockcroft, who can be contacted at j.k.cockcroft@ucl.ac.uk.

We have used the following criteria for inclusion of programs in this list:

(1) The software must have a relevance to powder diffraction. Programs that only use single-crystal diffraction data have been excluded.

(2) The software must be current *i.e.* there must be a valid URL or a contactable author.

(3) Software that pre-dates the year 2000 and that seems to have no current user base has been excluded. Readers who need access to older programs can find details on the CCP14 website.

At the time of writing (March 2019) all the URLs in the table are active, but it is of course impossible to guarantee that this will not change quite rapidly.

The programs are listed in alphabetical order with a brief description of their use, a primary reference and a URL or contact e-mail address that should enable the reader to get easy access to the required software. The online version of this chapter is probably more convenient in this respect, since it allows the reader to search for specific program functions.

Table 6.1.1
Software for powder diffraction

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
ACerS–NIST Phase Equilibria Diagrams Database	Phase-equilibria diagrams	Database	ACerS–NIST Phase Equilibria Diagrams Database (2013)		Commercial
ADM	Software suite including device control, pattern evaluation, qualitative and quantitative phase analysis, indexing, lattice-parameter refinement, crystal-size evaluation, microstress analysis, profile analysis and pattern simulation	Phase analysis, indexing, lattice-parameter refinement, crystal size, stress, profile analysis, pattern simulation		http://www.RMSKempten.de/	Commercial
American Mineralogist Crystal Structure Database (AMCSD)	Online database that includes every structure published in *The American Mineralogist*, *The Canadian Mineralogist*, *European Journal of Mineralogy* and *Physics and Chemistry of Minerals*, as well as selected data sets from other journals	Minerals, database	Downs & Hall-Wallace (2003)	http://rruff.geo.arizona.edu/AMSamcsd.php	Free to use
ANAELU	Computer-based tools for inferring single-crystal structures and fibre textures from two-dimensional diffraction diagrams	Modelling, glasses	Fuentes-Montero *et al.* (2011)	http://www.esrf.eu/computing/scientific/ANAELU/Anelu_Page.htm	Free
ARITVE	Modelling of glass structures using the Rietveld method	Modelling, glasses	Le Bail (1995, 2000)	http://sdpd.univ-lemans.fr/aritve.html	Free
ATOMS	Structure visualization. Part of the *SHAPE* software package	Structure visualization	Shape Software, 521 Hidden Valley Road, Kingsport, TN 37663, USA	http://www.shapesoftware.com/	Commercial
AUTOFP	GUI for highly automated Rietveld refinement using an expert system algorithm based on *FULLPROF*	Rietveld refinement	Cui *et al.* (2015)	http://pmedia.shu.edu.cn/autofp	Free
AUTOX	Autoindexing multiphase samples; included with *VMRIA*	Indexing	Zlokazov (1995); Bergmann *et al.* (2004)	http://www.ccp14.ac.uk/ccp/web-mirrors/vmria	Free
AXES	Program for X-ray powder diffraction data evaluation, specially designed for peak-shape analysis and data preparation for Rietveld refinement in connection with *FULLPROF*	Data conversion, peak-shape analysis	Mändar *et al.* (1996)	http://www.ccp14.ac.uk/ccp/web-mirrors/axes/~hugo/axes/	Free for academic use
AXES-20B	Estimation of crystal size and shape. Links to a wide range of programs and includes a range of data-processing and display functions	Phase identification, data conversion, structure visualization, peak location, peak profiling, indexing	Mändar & Vajakas (1998); Mändar *et al.* (1999)	http://www.ccp14.ac.uk/ccp/web-mirrors/axes/	Free
Balls&Sticks	Structure visualization and animation	Structure visualization	Ozawa & Kang (2004)	http://www.toycrate.org/	Free
BALSAC	Construction, visualization and interactive analysis of crystal lattices	Structure visualization	K. Hermann, Fritz-Haber-Institut der MPG, Berlin, Germany	http://www.fhi-berlin.mpg.de/~hermann/Balsac/	Free
BEARTEX	Texture analysis in polycrystalline materials	Texture analysis	Wenk *et al.* (1998)	http://eps.berkeley.edu/~wenk/TexturePage/beartex.htm	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
BGMN	Fundamental parameters, Rietveld refinement and quantitative-analysis software	Fundamental parameters, Rietveld refinement, quantitative analysis	Bergmann *et al.* (1998)	http://www.bgmn.de/methods.html	Free
Bilbao Crystallographic Server	Variety of symmetry tools including space-group retrieval tools, Wyckoff positions of space groups and group–subgroup relations	Symmetry	Aroyo *et al.* (2011)	http://www.cryst.ehu.es/	Free
B-IncStrDB	Database of incommensurate structures	Database	Kroumova *et al.* (2005)	http://www.cryst.ehu.es/icsdb/	Free
Bond Valence Wizard	Predicts interatomic distances in crystals by the bond-valence method	Bond-length prediction	Orlov *et al.* (1998); Brown (1977)	http://orlov.ch/bondval/	Free
BRASS 2	Rietveld refinement, Fourier-map calculation and visualization software	Rietveld refinement, visualization	Birkenstock *et al.* (2003)	http://www.brass.uni-bremen.de/	Free
BREADTH	Analysis of diffraction line broadening	Line broadening	Balzar (1995)	http://www.du.edu/~balzar/breadth.htm	Free
Cambridge Structural Database	Database (including structures derived from powder data) with associated software and software suites; organics and organometallics	Database	Groom *et al.* (2016)	http://www.ccdc.cam.ac.uk/	Commercial
CaRine	Visualization of lattices, surfaces, interfaces and diffraction patterns	Visualization	C. Boudias & D. Monceau, 1989–2004, CaRIne Crystallography	http://carine.crystallography.pagesperso-orange.fr/	Commercial
CASTEP	Calculates the properties of materials from first principles	Physical properties	Segall *et al.* (2002)	http://www.castep.org/	Free for European academics
CCP14	Web page with links to powder diffraction software	Software database	Stephenson *et al.* (2006)	http://www.ccp14.ac.uk/	Free
cctbx	A set of basic programming tools for X-ray crystallography	Programming	Grosse-Kunstleve *et al.* (2002)	https://github.com/cctbx/cctbx_project	Free
CDASH	Runs *DASH* over a network of computers	Structure solution	Spillman *et al.* (2015)	https://www.ccdc.cam.ac.uk/Solutions/PowderDiffraction/Pages/DASH.aspx	Commercial
Celref	Program for refining the unit cell	Unit-cell refinement	Laugier & Bochu (2004)	http://www.ccp14.ac.uk/ccp/web-mirrors/lmgp-laugier-bochu/	Free
CHECKCELL	Indexing and space-group determination, links into *Crysfire*	Indexing, space-group determination		http://www.ccp14.ac.uk/tutorial/lmgp/chekcellb.htm	Free
checkCIF	Cif checking service	CIF		http://journals.iucr.org/services/cif/checking/checkfull.html	Free
Chemical Database Service (CDS)	EPSRC-funded access to a large number of scientific databases, including all the main crystallographic databases, to UK-based academics and students	Database	Fletcher *et al.* (1996)	http://cds.dl.ac.uk/	Free within UK
CIFTOOLS	Includes two programs: *pdCIFplot* to plot Rietveld results from pdCIF files, and *CIFEDIT* to create, browse through and edit CIF files	CIF		ftp://ftp.ncnr.nist.gov/pub/cryst/cif/	Free
Cinema:Debye-Scherrer	Interactive visualization of multi-data-set Rietveld analyses	Data visualization	Vogel *et al.* (2018)	https://github.com/cinemascience/cinema_debye_scherrer	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
CMPR	Displays diffraction data, manual and auto-indexing, and peak fitting	Data visualization, indexing, peak fitting	Toby (2005)	http://www.ncnr.nist.gov/xtal/software/cmpr/	Free
CMWP-fit	Determination of microstructural parameters from diffraction profiles	Profile fitting	Ribárik *et al.* (2001)	http://csendes.elte.hu/cmwp/	Free
CONEX	Angular calibration and averaging of two-dimensional powder diffraction patterns	Two-dimensional data	Gommes & Goderis (2010)	Available from the authors	Free
Conograph	Integrated system with a graphical user interface for indexing	Indexing	Esmaeili *et al.* (2017)	https://osdn.net/projects/conograph/releases/	Free
ConQuest	Software for searching the Cambridge Structural Database	Database searching	Bruno *et al.* (2002)	http://www.ccdc.cam.ac.uk/	Commercial
ConvX	Data-conversion program that can convert multiple files at once. Also possible to select a particular angular range to convert	Data conversion	Bowden (2000)	http://www.ccp14.ac.uk/ccp/web-mirrors/convx/	Free
Corina	Structure generator for drug-like molecules	Structure prediction	Molecular Networks GmbH, Nuremberg, Germany; Sadowski *et al.* (1994); Schwab (2010)	https://www.mn-am.com/products/corina	Commercial
CRISP	Uses crystallographic image processing to extract information from electron micrographs	Electron diffraction	Hovmöller (1992)	http://www.calidris-em.com/crisp.php	Commercial
CRYSCA	Crystal-structure calculations for flexible molecules	Structure prediction	Schmidt & Kalkhof (1997)	Available from the authors	
Cryscon	Allows conversion between several popular crystallographic file formats	Data conversion	Eric Dowry, Shape Software, 521 Hidden Valley Road, Kingsport, TN 37663, USA	http://www.shapesoftware.com/	Shareware
Crysfire	Automatic powder-pattern indexing	Indexing	Shirley (2002)	http://www.ccp14.ac.uk/tutorial/crys/, http://www.ccp14.ac.uk/ccp/web-mirrors/crys-r-shirley/	Free
CrystalDiffract	Data processing and visualization	Peak fitting	CrystalMaker Software Ltd, 5 Begbroke Science Park, Sandy Lane, Yarnton, OX5 1PF, UK	http://crystalmaker.com/crystaldiffract/index.html	Commercial
Crystal Maker X	Visualization, structure design, simulation and 3D printing package	Visualization, simulation	CrystalMaker Software Ltd, 5 Begbroke Science Park, Sandy Lane, Yarnton, OX5 1PF, UK	http://www.crystalmaker.com/	Commercial
Crystal Studio	Visualization including surfaces, interfaces, defects and simulation of diffraction data	Visualization, defects, data simulation	Crystalsoftcorp, PO Box 7006, Wattle Park, VIC 3128, Australia	http://www.crystalsoftcorp.com, http://www.crystal0studio.com/	Commercial
Crystallographica	A software toolkit for crystallography	Visualization, pattern simulation	Oxford Cryosystems (1997)	http://www.oxcryo.com/cg/	Free
Crystallography Open Database (COD)	Open-access database including predicted structures, covering organics, inorganics, metal–organics and minerals	Database	Grazulis *et al.* (2009)	http://www.crystallography.net/	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
CRYSTMET	Database of metals, alloys and intermetallics	Database	White *et al.* (2002); Toth Information Systems, Inc., 2045 Quincy Avenue, Ottawa, Ontario, K1J 6B2, Canada	https://cds.dl.ac.uk/cds/datasets/crys/mdf/llmdf.html	Free to UK academic users
DAJUST	Intensity extraction and space-group determination. Part of the *XLENS* package	Space-group determination, cell-parameter refinement, profile fitting, Le Bail method	Vallcorba *et al.* (2012)	https://departments.icmab.es/crystallography/news/42-pdsoftware	Free to non-commercial users
DANSE	General software for neutron scattering	Neutron scattering	Cummings *et al.* (2002)	http://wiki.cacr.caltech.edu/danse/index.php/Main_Page	Free
DASH	Software for solving crystal structures from X-ray powder diffraction patterns	Structure solution	David *et al.* (2006)	http://www.ccdc.cam.ac.uk/products/powder_diffraction/dash/	Commercial
Database of Zeolite Structures	Provides structural information on all of the zeolite framework types that have been approved by the Structure Commission of the International Zeolite Association (IZA-SC)	Database	Baerlocher *et al.* (2003)	http://www.iza-structure.org/databases/	Free
DataScan	Diffractometer automation hardware and software	Instrumentation, diffractometer control	Materials Data, Inc., 2551 Second Street, Livermore, CA 94550, USA	http://www.materialsdata.com/ds.htm	Commercial
Datasqueeze	Graphical interface for analysing data from two-dimensional X-ray diffraction detectors	Two-dimensional data analysis	Heiney (2002)	http://www.physics.upenn.edu/~heiney/datasqueeze/index.html	Free
DDM	Refinement using the Rietveld method or derivative difference minimization	Rietveld refinement, derivative difference refinement	Solovyov (2004)	https://sites.google.com/site/ddmsuite/	Free
Debussy 2.0	Analysis of powder diffraction data from nanocrystalline, defective and/or nonperiodic materials	Nanocrystalline and non-periodic materials, defects	Cervellino *et al.* (2015)	http://debussy.sourceforge.net/debussy/debussy.html	Free
DEBVIN	Rietveld refinement with the use of generalized coordinates	Rietveld refinement, polymers	Brückner & Immirzi (1997)	https://vdocuments.site/debvin-a-program-for-Rietveld-refinement-with-generalized-coordinates.html	Free
decryst	Software suite for structure determination from powder diffraction using the direct-space method	Structure solution	Liu (2018)	https://gitlab.com/CasperVector/decryst/	Free
Diamond	Crystal and molecular structure visualization and exploration	Structure visualization	Crystal Impact – K. Brandenburg and H. Putz GbR, Postfach 1251, D-53002 Bonn, Germany	http://www.crystalimpact.com/	Commercial
DICVOL	Automatic indexing	Indexing	Boultif & Louër (2004)	http://www.ccp14.ac.uk/ccp/web-mirrors/dicvol/	Free
DIFFaX	Simulation of powder diffraction patterns for faulted materials	Stacking faults, simulation	Treacy *et al.* (1991)	http://www.public.asu.edu/~mtreacy/DIFFaX.html	Free
DIFFaX+	A modified version of *DIFFaX* for the refinement of disordered stack materials	Refinement, disordered stack materials	Leoni *et al.* (2004)	Available from the author (matteo.leoni@unitn.it) on request	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
Diffpy-CMI	Python software for diffraction analysis and the study of the atomic structure of materials	Modelling	See https://www.diffpy.org/publications.html	http://diffpy.org	Free
DIFFRAC.EVA	Data processing, phase identification and quantitative analysis. Cluster analysis allows high-throughput screening	Profile fitting, cluster analysis, quantitative phase analysis	Bruker AXS GmbH, Oestliche Rheinbrueckenstr. 49, D-76187 Karlsruhe, Germany	https://www.bruker.com/products/x-ray-diffraction-and-elemental-analysis/x-ray-diffraction/xrd-software/eva/overview.html	Commercial
DIFFRAC.TOPAS	Profile and structure analysis (see *TOPAS*)	Profile analysis, Rietveld refinement	Bruker AXS GmbH, Oestliche Rheinbrueckenstr. 49, D-76187 Karlsruhe, Germany	https://www.bruker.com/products/x-ray-diffraction-and-elemental-analysis/x-ray-diffraction/xrd-software/topas.html	Commercial
DISCUS	Simulates defect structures and diffuse scattering, plus the simulation of perfect structures of non-crystalline materials	Defect structures, simulation	Proffen & Neder (1997, 1999)	https://www.xray.cz/ecm-cd/soft/xray/general/discus/discus/disfeat.html	Free
DLS-76	Structure refinement with distance constraints; part of *FOCUS*	Rietveld refinement	Baerlocher *et al.* (1976, 1977)	https://github.com/stefsmeets/focus_package, http://www.crystal.mat.ethz.ch/Software/index.html	Free
DRAWxtl	Open-source program for producing crystal-structure drawings	Visualization	Finger *et al.* (2007)	http://www.lwfinger.net/drawxtl/	Free
DRXWin	Diffraction data manipulation and qualitative analysis	Visualization, qualitative phase analysis, peak search	Vicent Primo Martín, El Instituto de Ciencia de los Materiales, Universitat de Valencia, Avda. Blasco Ibáñez, 13, 46010 Valencia, Spain	http://www.ccp14.ac.uk/ccp/web-mirrors/drxwin/drxwin/	Free
Dysnomia	Calculates electron and nuclear densities from observed structure factors by the maximum-entropy method	Electron and nuclear density calculations	Momma *et al.* (2013)	http://jp-minerals.org/dysnomia/en/	Free
Eager	Genetic algorithm for crystal structure solution from powder diffraction data	Structure solution	Harris *et al.* (2004)	Contact K. D. M. Harris	
EFLECH/INDEX	Whole-pattern indexing	Indexing	Bergmann (2007)	http://www.bgmn.de/indexpgm.html	Free
ELD	Quantitative information from electron-diffraction patterns	Electron diffraction	Calidris, Sweden	http://www.calidris-em.com/eld.php	Commercial
enCIFer	Viewing and editing CIF files	CIF editing	Allen *et al.* (2004)	https://www.ccdc.cam.ac.uk/Community/csd-community/encifer/	Free
Endeavour	Direct-space method for *ab initio* solution of structures from powder diffraction data by combined global optimization of pattern difference and potential energy	Structure solution	Putz *et al.* (1999)	http://www.crystalimpact.com/endeavour/	Commercial
EPCryst	Structure solution from powder diffraction data using models generated by an equivalent-position combination algorithm based on unit-cell content and space-group information	Structure solution	Deng & Dong (2011)	http://www.epcryst.com	Free
ESPOIR	Structure solution by Monte Carlo analysis of powder diffraction data	Structure solution	Le Bail (2001)	http://www.cristal.org/sdpd/espoir/	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
EXPGUI	Graphical interface for *GSAS*	Rietveld refinement, visualization	Toby (2001)	http://www.ncnr.nist.gov/programs/crystallography/software/expgui/	Free
EXPO2014	Structure-solution toolkit for phasing crystal structures from powder data	Structure solution	Altomare *et al.* (2013)	http://www.ba.ic.cnr.it/softwareic/expo/expo2014-installation/	Free for non-profit users
ExtSym	Space-group assignment. Bundled with *DASH* but can be obtained separately from Anders Markvardsen	Space-group determination	Markvardsen *et al.* (2001)	http://www.markvardsen.net/projects/ExtSym/main.html	Free
FABLE	Reads many X-ray detector image formats	Data processing	Schmidt *et al.* (2009)	http://sourceforge.net/projects/fable/	Free
FAULTS	Refinement of structures with extended defects, based on *DIFFaX*	Defect structures, simulation	Casas-Cabanas *et al.* (2016)		Free
FIT	Decomposition of powder diffraction patterns and profile analysis of pair correlation functions	Profile analysis, PDF analysis	Petkov & Bakaltchev (1990)	http://web.pa.msu.edu/people/petkov/software.html	Free for academic use
FIT2D	Calibration and correction of detector distortions, integration of two-dimensional data to a variety of one-dimensional scans, and one- and two-dimensional model fitting	Data analysis, visualization	Hammersley (1998, 2016); Hammersley *et al.* (1996)	http://www.esrf.fr/computing/scientific/FIT2D/	Free
FitAllb	Fitting centre-of-mass grain positions, orientation and elastic strain tensors	Strain	Oddershede *et al.* (2010)	https://sourceforge.net/p/fable/wiki/FitAllB/	Free
FitGISAXS	Modelling and analysis of grazing-incidence small-angle X-ray scattering data	GISAXS	Babonneau (2010)	https://www.pprime.fr/?q=en/node/1013; contact D. Babonneau, david.babonneau@univ-poitiers.fr	Free
FlexCryst	Program suite including crystal-structure prediction, structure determination and clustering	Structure prediction, structure determination	Hofmann & Apostolakis (2003)	http://www.flexcryst.com/html/home.pdf	Commercial
FOCUS	Automated structure determination of zeolites. Can use electron-diffraction data	Structure determination, zeolites	Grosse-Kunstleve *et al.* (1997)	https://github.com/stefsmeets/focus_package	Free
FOX	*Ab initio* structure determination using global-optimization algorithms, suitable for any type of crystal structure (organic, inorganic including automatic correction of special positions); can combine several data sets	Structure solution	Favre-Nicolin & Cerný (2002)	http://objcryst.sourceforge.net/Fox/	Free
FOXGrid	Structure solution using *FOX* with distributed computing	Structure solution	Rohlíček *et al.* (2007)	https://fox.vincefn.net/Manual/Fox.Grid	Free
FULLPAT	Full-pattern quantitative phase analysis merging the advantages of existing full-pattern fitting methods with the traditional reference intensity ratio method. Coded into Excel	Quantitative phase analysis	Chipera & Bish (2002)	http://www.ccp14.ac.uk/ccp/web-mirrors/fullpat/	Free
FULLPROF	Rietveld refinement and pattern matching	Rietveld refinement, pattern matching	Rodriguez-Carvajal (1990)	https://www.ill.eu/sites/fullprof/	Free
GDASH	Structure solution using grid computing	Structure solution	Griffin *et al.* (2009)	Contact Tom Griffin, tom.griffin@stfc.ac.uk	
GEST	Structure solution using a genetic algorithm	Structure solution	Feng & Dong (2007)	Contact Zhen Jie Feng, fengzhenjie@gmail.com	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
GETSPEC	Calculates the symmetry operators and special positions for any setting of any space group based on the Hall space-group symbol	Symmetry	Altermatt & Brown (1987)	http://www.ccp14.ac.uk/ccp/web-mirrors/i_d_brown/getspec/	Free
Gnu Xtal System	Set of portable crystallographic routines	Software development		http://xtal.sourceforge.net/	Free
GrainSpotter	Indexing grains in monophase crystalline materials	Indexing	Schmidt (2014)	https://sourceforge.net/p/fable/wiki/grainspotter/	Free
Gretep	Displacement-ellipsoid plot structure viewing and analysis. Part of the *LMGP* suite	Visualization	Laugier & Bochu (2004)	http://www.ccp14.ac.uk/tutorial/lmgp/#gretep, http://www.ccp14.ac.uk/ccp/web-mirrors/lmgp-laugier-bochu/	Free
GRINSP	Inorganic structure prediction	Structure prediction	Le Bail (2005)	http://www.cristal.org/grinsp/	Free
GSAS	Comprehensive system for the refinement of structural models to both X-ray and neutron diffraction data. Superseded by *GSAS-II*	Pattern fitting, structure solution, Rietveld refinement, visualization	Larson & Von Dreele (2004)	http://subversion.xray.aps.anl.gov/trac/EXPGUI	Free
GSAS-II	Open-source Python project that addresses all types of crystallographic studies, from simple materials through macromolecules, using both powder and single-crystal diffraction and with both X-ray and neutron probes	Pattern fitting, structure solution, Rietveld refinement, visualization	Toby & Von Dreele (2013)	https://subversion.xray.aps.anl.gov/trac/pyGSAS	Free
gsaslanguage	A language that provides input to and processes output from the *GSAS* package	Scripting	Vogel (2011)	http://code.google.com/p/gsaslanguage/	Free
GSASIIscriptable	Scripting interface for *GSAS-II*	Scripting	O'Donnell *et al.* (2018)	https://gsas-ii.readthedocs.io/en/latest/GSASIIscriptable.html	Free
GudrunN and *GudrunX*	Programs for correcting raw neutron and X-ray total-scattering data to differential cross sections	Data processing, neutron diffraction, total scattering	Soper & Barney (2011)	In-house software at ISIS	
HELIX	Simulation of helical diffraction	Powder-pattern calculation	Knupp & Squire (2004)	https://www.diamond.ac.uk/Instruments/Soft-Condensed-Matter/small-angle/SAXS-Software/CCP13.html	Free
Hypertext book of crystallographic space-group diagrams and tables	Space-group diagrams	Space-group information	Cockcroft (1999)	http://img.chem.ucl.ac.uk/sgp/	Commercial
ICDD Powder Diffraction File	Comprehensive powder database: PDF-4+, PDF-4 organics and PDF-2, plus derivatives	Database, phase identification	International Centre for Diffraction Data, 12 Campus Boulevard, Newtown Square, PA, 19073–3273, USA	http://www.icdd.com/	Commercial
IGOR Pro	Scientific data-analysis software	Data analysis	Kline (2006)	https://www.wavemetrics.com/products/igorpro	Commercial
ImageD11	Python codes for processing diffraction data from 2D detectors at the ID11 beamline at the ESRF	Data processing, neutron diffraction	Wright (2011)	http://sourceforge.net/projects/fable/files/ImageD11	Free
Inorganic Crystal Structure Database (ICSD)	Database of inorganic structures	Database	Belsky *et al.* (2002)	http://www2.fiz-karlsruhe.de/icsd_home.html	Commercial

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
input4MAUD	Input of two-dimensional data into *MAUD*	Data conversion	Raue (2014)	http://kristall.uni-mki.gwdg.de/Docs/raue/input4MAUD/main.html	Free
International Tables Online	Online editions of all volumes of *International Tables for Crystallography*, including Volume A (*Space-Group Symmetry*), and an extensive symmetry database	Space-group information, database	*International Tables Online* (2019)	https://it.iucr.org	Commercial
iotbx.cif	Input, output and validation of CIFs	CIF	Gildea *et al.* (2011)	https://cci.lbl.gov/cctbx_docs/iotbx/iotbx.cif.html	Free
ISAACS	Interactive structure analysis of amorphous and crystalline systems	Structure analysis, amorphous materials	Le Roux & Petkov (2010)	http://isaacs.sourceforge.net	Free
IsoDEC	Calculation of diffraction elastic constants	Strain	Gnäupel-Herold (2012)	https://www.ncnr.nist.gov/xtal/software/isodec	Free
IsoStar	Information on intermolecular interactions derived from small-molecule crystal structures in the Cambridge Structural Database and from protein–ligand interactions observed in the Protein Data Bank (PDB)	Database	Bruno *et al.* (1997)	https://www.ccdc.cam.ac.uk/solutions/csd-system/components/isostar/	Commercial
ISOTROPY	Applies group-theoretical methods to the analysis of phase transitions in crystalline solids	Space-group determination	Stokes & Hatch (2002)	http://stokes.byu.edu/isotropy.html	Free web service
ITO	Powder-pattern indexing. Incorporated into many other packages, both free and commercial	Indexing	Visser (1969)	http://sdpd.univ-lemans.fr/ftp/ito13.zip	Free/commercial
JADE	Comprehensive powder diffraction data-processing suite. *JADE Standard* is available as perpetual license and *JADE Pro* as an annual subscription	Cluster analysis, data conversion, indexing, Le Bail fitting, Pawley fitting, peak location, peak profiling, phase identification, powder-pattern viewing, quantitative phase anaysis, Rietveld refinement, size–strain analysis	Materials Data, Inc. (2016)	http://www.materialsdata.com/products.htm; http://www.icdd.com/	Commercial
Jana2006	Analysis of incommensurate, modulated and composite structures, as well as standard Rietveld refinement	Le Bail fitting, Rietveld refinement, Fourier-map calculation and visualization, structure solution	Petříček *et al.* (2000); Dusek *et al.* (2001)	http://jana.fzu.cz/	Free
JEMS	Simulation of high-resolution TEM (HRTEM), CBED, PED and SAED patterns, and simulation of powder diffraction rings	Electron diffraction, simulation	Stadelmann (2003)	http://www.jems-saas.ch/Home/jemsWebSite/jems.html	Free for students
J-ICE	Visualization of crystallographic and electronic properties using *Jmol*	Visualization, data conversion	Canepa *et al.* (2011)	http://j-ice.sourceforge.net	Free
Jpowder	JAVA data viewer	Data visualization	Markvardsen *et al.* (2010)	https://sourceforge.net/projects/jpowder/	Free
KoalaRiet	Powder-pattern viewing, peak profiling and Rietveld refinement, fundamental parameters approach	Pattern visualization, peak fitting, Rietveld refinement	Cheary & Coelho (1996)	http://www.ccp14.ac.uk/	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
LABOTEX	Crystallographic texture analysis of rocks, semiconductors and superconductors, ceramics and composites, polymers, metals and alloys	Texture analysis	Pawlik & Ozga (1999)	http://www.labosoft.com.pl/	Commercial
LAPOD	Refinement of lattice parameters using optimal regression	Unit-cell refinement	Dong & Langford (2000)	http://www.ccp14.ac.uk/ccp/web-mirrors/powderx/lapod/	Free
LauePt	GUI for Laue-pattern simulation and analysis	Data analysis, simulation	Huang (2010)	http://www.ccp14.ac.uk/ccp/web-mirrors/xianrong-huang/	Free
MacDiff	Analysis and display of powder data on Macintosh platforms	Database, phase identification, data conversion	Petschick (2001)	http://www.geol-pal.uni-frankfurt.de/Staff/Homepages/Petschick/MacDiff/MacDiffInfoE.html	Free
MATCH!	Compares the diffraction pattern of the unknown to a database containing reference patterns; additional knowledge such as known phases, elements or density can also be used	Phase identification, quantitative phase analysis	Crystal Impact – K. Brandenburg and H. Putz GbR, Postfach 1251, D-53002 Bonn, Germany	http://www.crystalimpact.com/match/	Commercial
Materials Studio	Multipurpose suite	Indexing, model building, structure solution, visualization		http://accelrys.com/products/collaborative-science/biovia-materials-studio/	Commercial
MAUD	Rietveld-based program for combined analysis. Can be used to fit diffraction, fluorescence and reflectivity data collected using X-rays, neutrons or electrons	Data integration, indexing, space-group assignment, texture analysis, size–strain analysis, Rietveld refinement, quantitative phase analysis	Lutterotti *et al.* (1999)	http://maud.radiographema.eu/	Free
MCE-Marching Cubes	Interactive visualization of electron and other density maps, optimized for small molecules	Fourier-map calculation and visualization	Husák & Kratochvíl (2003)	https://sourceforge.net/projects/mce-marching-cube-eld/	Free
McMaille	Indexing using Monte Carlo methods	Indexing	Le Bail (2004)	http://www.cristal.org/McMaille	Free
Mercury	Statistical analysis of data from the Cambridge Structural Database, structure visualization and simulation of powder patterns	Structure visualization	Sykes *et al.* (2011)	http://www.ccdc.cam.ac.uk/products/mercury/	Free; commercial version has more functions
MINCRYST	Contains crystal-structure data for minerals	Database	Chichagov *et al.* (2001)	http://database.iem.ac.ru/mincryst/	Free
The Mineralogy Database	Includes information on the crystal structures, powder diffraction patterns, chemical composition, and physical and optical properties of minerals	Database		http://webmineral.com	Free
Mogul	Validation of bond lengths, angles and torsions against the Cambridge Structural Database	Structure validation	Bruno *et al.* (2004)	http://www.ccdc.cam.ac.uk/products/csd_system/mogul/	Commercial
MOPAC2016	Semi-empirical quantum chemistry calculations. *Mercury* has an interface to *MOPAC*	Structure validation, structure building	Stewart (2012)	http://openmopac.net	Free for academic use
Mstruct	Microstructure analysis using powder diffraction	Microstructure analysis	Matěj *et al.* (2014)	http://www.xray.cz/mstruct/	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
Multifit/Polydefit	Open-source IDL software package for data analysis of synchrotron-based plasticity, rheology or other time-dependent experiments	Texture analysis	Merkel & Hilairet (2015)	http://merkel.texture.rocks/Multifit-Polydefix/	Free
MultiRef	*MATLAB* framework for *GSAS*; Rietveld refinement of multiple powder diffractograms from *in situ*, scanning or diffraction tomography experiments	Rietveld refinement	Frølich & Birkedal (2015)	http://chem.au.dk/en/research/research-areas/inorganicchemistrymaterialschemistry/biological-and-bioinspired-materials/multiref/downloads/	Free
NanoPDF64	Software package for analysis of pair-distribution functions of nanocrystals, also capable of calculating theoretical powder diffraction patterns and pair-distribution functions for atomistic models of nanocrystals	PDF analysis	Skrobas *et al.* (2017)	http://www.unipress.waw.pl/nanopdf	Free
NEWMOD II	Modelling of interstratified layer structures	Powder-pattern calculation	Yuan & Bish (2010)	https://newmod-for-clays.com	Commercial
Nickel–Nichols Mineral Database	Mineral database	Phase identification	The Nickel–Nichols Mineral Database, Materials Data, Inc., 1224 Concannon Blvd, Livermore, CA 94550, USA; Nickel & Nichols (1991)	http://www.materialsdata.com/MINERALS.htm	Free
Nika	Open-source *Igor Pro*-based program for reduction of two-dimensional scattering data from area-detector small- and wide-angle scattering instruments. Can be used in transmission and grazing-incidence geometries	SAXS, WAXS	Ilavsky (2012)	https://usaxs.xray.anl.gov/software/nika	Free
NXS	Library for neutron cross-section calculations	Neutron diffraction	Boin (2012)	https://www.helmholtz-berlin.de/people/boin/nxs_en.html	Free
OpenBabel	Open-source chemistry toolbox, allowing users to search, convert, analyse or store data from molecular modelling, chemistry, solid-state materials, biochemistry or related areas	File conversion	O'Boyle *et al.* (2011)	http://openbabel.sourceforge.net/	Free
OpenGenie	Neutron-data analysis	Powder-pattern visualization	Akeroyd *et al.* (1999)	http://www.opengenie.org/Main_Page	Free
PASCal	Online tool for determining principal coefficients of thermal expansion and compressibilities using variable-pressure and variable-temperature lattice-parameter data	Strain	Cliffe & Goodwin (2012)	http://pascal.chem.ox.ac.uk	Free web access
PATE	*GSAS* powder-pattern extractor	Data conversion		http://www.ccp14.ac.uk/ccp/web-mirrors/scott-belmonte-software/pate/	Free
PCED3	Simulation of polycrystalline electron diffraction and phase identification	Electron diffraction, phase identification		http://www.unl.edu/ncmn-cfem/xzli/download	Free
PCOD	Open database of structures of inorganic compounds predicted or enumerated mainly using *ZEFSA II* or *GRINSP*	Phase identification, database		http://www.crystallography.net/pcod/	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
PDXL 2	Provides various analysis tools such as automatic phase identification, quantitative analysis, crystallite-size analysis, lattice-constants refinement, Rietveld analysis, *ab initio* structure determination and data clustering. Peak shapes can be modelled using a fundamental-parameters approach	Rietveld refinement, quantitative analysis, phase identification, structure determination	Rigaku (2014)	https://www.rigaku.com/en/service/software/pdxl	Commercial
PeckCryst	Molecular crystal structure determination from powder diffraction data using a particle swarm optimization algorithm	Structure solution	Feng *et al.* (2009)	Contact J. C. Zhang, jczhang@shu.edu.cn	Free
PLATON	Implements a large variety of standard geometrical calculations and tests (*e.g.* for missing symmetry, voids in the lattice *etc.*), and includes utilities for cell transformation and graphics. Used in *checkCIF*	Data conversion, space-group assignment, structure refinement, H-atom placement, structure validation, powder-pattern calculation, structure visualization	Spek (1998, 2003)	http://www.cryst.chem.uu.nl/platon/	Free
PM2K	Full-pattern fitting allowing microstructural investigation of nanocrystalline materials. Includes analysis of size broadening due to an analytical or to a generic (unconstrained) distribution of crystallites, the presence of dislocations, stacking faults and antiphase boundaries	Whole-powder-pattern modelling	Leoni *et al.* (2006)	Contact M. Leoni, matteo.leoni@unitn.it	Free for academic use
PolySNAP3	Clustering powder diffraction, XRF and spectroscopic data. Semi-quantitative analysis	Cluster analysis, phase analysis	Barr *et al.* (2009)	http://www.bruker.com/	Commercial
popLA	Pole-figure evaluation using the harmonic and WIMV methods	Texture analysis	Kocks *et al.* (1998)	http://lansce.lanl.gov/facilities/lujan/instruments/hippo/popLA.php	Free
Powder Cell	Represents the crystal structure and the corresponding powder pattern simultaneously. Translations and rotations of a preselected part of the asymmetric unit allow manipulation of the structure	Data conversion, powder-pattern calculation, powder-pattern viewing, Le Bail fitting, size–strain analysis, Rietveld refinement, quantitative phase analysis, structure visualization	Kraus & Nolze (1996)	http://powdercell-for-windows.software.informer.com/2.4/	Free
Powder3D	Multiple-pattern data reduction and graphical presentation. Part of *Materials Studio*	Data integration, data conversion, powder-pattern viewing, peak location	Hinrichsen *et al.* (2008)	https://www.fkf.mpg.de/4708688/Powder-3D-Software	Free
PowderX	Uses include plotting X-ray patterns, data smoothing, background subtraction, α_2-peak elimination, peak search, indexing, zero-angle error correction and data-format conversions	Data conversion, powder-pattern viewing, peak location, indexing	Dong (1999)	http://www.ccp14.ac.uk/ccp/web-mirrors/powderx/Powder/	Free
PowDLL	.NET dynamic link library used for interconversion between variable formats of X-ray powder diffraction files	Data conversion	Kourkoumelis (2005)	http://users.uoi.gr/nkourkou/powdll.htm	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
PRODD	Refinement of crystal and magnetic structures from powder diffraction data, can be used with time-of-flight and constant-wavelength neutron data as well as synchrotron X-ray data	Pawley fitting, Rietveld refinement, proteins	Wright (2004); Wright & Forsyth (2000); Wright *et al.* (2007)	http://www.ccp14.ac.uk/ccp/web-mirrors/prodd/~jpw22/	Free
PROFEX	A platform-independent open-source graphical user interface for the Rietveld refinement program *BGMN*. Reads and converts a variety of proprietary raw data formats	Rietveld refinement, data conversion	Doebelin & Kleeberg (2015)	http://profex.doebelin.org/	Free
Profil	Rietveld refinement and utilities. Can be used for organics and organometallics requiring restrained refinement	Unit-cell refinement, Rietveld refinement, Fourier-map calculation, visualization, data conversion	Cockcroft (1994)	http://img.chem.ucl.ac.uk/www/cockcroft/profil.htm	Free for academic use
publCIF	Editing, validating and formatting CIF files	CIF editing	Westrip (2010)	http://journals.iucr.org/services/cif/publcif/	Free
PyCifRW	Support for reading and writing of CIF files using Python, with optional validation against DDL dictionaries	CIF editing	Hester (2006)	https://pypi.org/project/PyCifRW/4.3/	Free
PyMOL	A comprehensive software package for rendering and animating 3D structures	Structure visualization		https://pymol.org/2/	Commercial
Quanto	Allows automatic estimation of the weight fraction of each crystalline phase in a mixture. The amorphous content can be estimated using the internal-standard method, and corrections for preferred orientation and microabsorption effects are available	Quantitative phase analysis	Altomare *et al.* (2001)	http://www.ic.cnr.it/	Free
RIETAN-FP	A package of programs for analysing crystal structures from X-ray and neutron powder diffraction data and visualizing the results in three dimensions, along with electronic-state calculations	Rietveld refinement, data conversion	Izumi & Momma (2007)	http://fujioizumi.verse.jp/download/download_Eng.html	Free
Rietica	Aids the creation and updating of Rietveld input files for and provides point-and-click control of the Rietveld program *LHPM*	Le Bail fitting, Rietveld refinement, visualization	Hunter (1998)	http://www.rietica.org/	Free
RMC++	Reverse Monte Carlo modelling of the structure of disordered materials, mainly using diffraction data, but additional information such as EXAFS data and different constraints can also be used	PDF analysis	Evrard & Pusztai (2005)	http://www.szfki.hu/~nphys/rmc++/opening.html	Free
RMCAW95	Uses the reverse Monte Carlo method for modelling both lattice and magnetic disorder in powder crystalline materials by direct calculation of the structure factor	PDF analysis	Mellergård & McGreevy (1999)	http://www.cristal.org/glasses/rmca/rmcaw95.html	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
RMCprofile	Built from the original *RMCA* code of McGreevy & Pusztai to determine the local structure of crystalline materials while still being capable of analysing disordered systems. Can be used to fit many data types (including total scattering, EXAFS, diffuse scattering) simultaneously	PDF analysis	Tucker *et al.* (2007)	http://www.rmcprofile.org	Free
ROCKJOCK	Quantitative analysis of mineralogical samples with or without using an internal standard by automatically fitting the sum of stored X-ray diffraction patterns of pure standard minerals to the measured pattern	Quantitative phase analysis, minerals	Eberl (2003)	http://pubs.er.usgs.gov/publication/ofr200378	Free
Siroquant	Comes with a comprehensive database of over 1800 phases. Phases from public sources such as the ICSD and AMCSD can also be added	Phase identification	Sietronics (2012)	http://www.siroquant.com	Commercial
SPEC	Software for the control of data acquisition. Includes *C-PLOT* for data display and analysis	Instrumentation	SPEC, Certified Scientific Software, PO Box 390640, Cambridge, MA, 02139-0007, USA	http://www.certif.com/	Commercial
STEREOPOLE	Analysis of X-ray diffraction pole figures, allowing experimental data to be compared graphically with simulated results, and epitaxic relationships between up to five different crystal layers to be evaluated	Texture analysis	Salzmann & Resel (2004)	http://www.if.tugraz.at/amd/stereopole/	Free
Struvir	Converts *STRUPLO* data files into Virtual Reality Modeling Language (VRML) for 3D visualization	Visualization	Le Bail (1996); Fischer (1985)	http://www.cristal.org/vrml/struvir.html	Free
SUPERFLIP	Structure solution from diffraction data using charge flipping. Can solve periodic structures, incommensurately modulated structures and the structures of quasicrystals from X-ray and neutron diffraction data	Structure solution	Palatinus & Chapuis (2007)	http://superflip.fzu.cz	Free
TOPAS and *TOPAS-Academic*	Nonlinear least-squares optimization programs written in C++, allowing users to easily modify program functionality to suit the problem at hand	Peak fitting, Le Bail fitting, Pawley fitting, Rietveld refinement, PDF analysis, indexing, structure solution, charge flipping, magnetic structures, stacking-fault analysis	Coelho (2018)	https://www.bruker.com/products/x-ray-diffraction-and-elemental-analysis/x-ray-diffraction/xrd-software/topas.html, http://www.topas-academic.net	Free
VALENCE	Calculates bond valences from bond lengths and *vice versa*. Can also calculate bond-valence sums and average bond lengths, and can determine bond-valence parameters from the bonding environments of various cations	Structure validation	Brown (1996)	http://netlib.ccp14.ac.uk/ccp/web-mirrors/valence	Free
VMRIA	Full-profile analysis of neutron-diffraction time-of-flight data for multiphase samples. Includes *Autox*	Rietveld refinement, indexing	Zlokazov & Chernyshev (1992); Zlokazov (2003)	http://www.ccp14.ac.uk/ccp/web-mirrors/vmria/	Free

Program	Description	Function(s)	Reference(s)	URL or other source	Availability
WinPLOTR	A graphical user interface for displaying powder patterns; part of *FULLPROF*	Powder-pattern viewing		http://www.cdifx.univ-rennes1.fr/winplotr/readme.htm	Free
WinPSSP	Uses direct-space methods to solve the crystal structures of small-molecule organic materials from X-ray powder diffraction data	Structure solution	Pagola *et al.* (2017)	http://users.uoi.gr/nkourkou/winpssp/	Free
WinXPow	Comprehensive package for data collection, profile fitting, indexing, and size–strain and crystallinity analysis	Phase identification, profile fitting, indexing, size–strain analysis, crystallinity	STOE & Cie GmbH, Hilpertstr. 10, D-64295 Darmstadt, Germany	https://www.stoe.com/product/software-powder-xrd/	Commercial
XDrawChem	Two-dimensional molecule drawing program for Unix operating systems	Model building	Herger (2002)	http://xdrawchem.sourceforge.net/	Free
xINTERPDF	Analysis of intermolecular pair-distribution functions of organic compounds from X-ray total-scattering data	PDF analysis	Shi (2018)	https://github.com/curieshicy/xINTERPDF	Free
XLENS	Uses Patterson-function direct methods instead of the modulus function. Well suited for handling powder diffraction data for organic compounds	Structure solution	Rius (2011, 2013)	https://departments.icmab.es/crystallography/software	Free for academic use
xPDFsuite	Suite of algorithms and software for pair-distribution-function analysis	PDF analysis	Juhás *et al.* (2013)	https://www.diffpy.org/products/xPDFsuite.html	Free for academic use
X'Pert HighScore Plus	Integrated powder-processing suite including profile fitting, structure solution, Rietveld refinement, quantitative analysis and cluster analysis	Cluster analysis, data conversion, indexing, Le Bail fitting, Pawley fitting, peak location, peak profiling, phase identification, powder-pattern viewing, quantitative phase analysis, Rietveld refinement, size–strain analysis	Malvern Panalytical BV, De Schakel 18, Kamer 50, Eindhoven, 5651 GH, Netherlands	https://www.malvernpanalytical.com/products/category/software/x-ray-diffraction-software/highscore-with-plus-option	Commercial
Xpowder	Identification, quantification and characterization of the crystalline components of solids, including natural minerals, artificial compounds and biological crystals	Phase identification	Quetzal Com S. L., La Carrera 5, 18110 HIJAR– Las Gabias, Granada, Spain	http://www.xpowder.com/	Commercial
XRD2DScan	Display and analysis of two-dimensional X-ray diffraction patterns collected with an area detector	2D data	Rodriguez-Navarro (2006)	http://www.ugr.es/~anava/xrd2dscan.htm	Free
XRDUA	Reconstruction of crystalline phase distribution maps from two-dimensional diffraction patterns collected by scanning and tomographic X-ray powder diffraction	Data processing, phase distributions	de Nolf (2014)	http://xrdua.ua.ac.be	Free
ZEFSA II	Zeolite structure solution using a biased Monte Carlo scheme	Structure solution, zeolites	Falcioni & Deem (1999)	http://www.mwdeem.rice.edu/zefsaII/	Free

Cervellino, A., Frison, R., Bertolotti, F. & Guagliardi, A. (2015). *DEBUSSY 2.0: the new release of a Debye user system for nanocrystalline and/or disordered materials. J. Appl. Cryst.* **48**, 2026–2032.

7.1. Macromolecular powder diffraction

I. Margiolaki

7.1.1. Introduction

The preparation of a powder sample is frequently observed, as microcrystalline powders are obtained for many proteins by batch precipitation (Von Dreele, 2003). The size of individual crystallites (~0.1–1 µm) in such precipitates is usually far too small for single-crystal diffraction studies, but it is (in many cases) ideal for powder diffractometry. In the last ten years, the use of powder data with macromolecules has gone from being an ambitious suggestion to a respectable method. To date, a series of experiments and data analyses has been carried out; these experiments establish the validity of the methodology (Von Dreele, 2003; Margiolaki & Wright, 2008; Karavassili & Margiolaki, 2016). Although methods for phasing and structure solution are still under development, molecular-replacement and structure-refinement methods are now mature enough for use by the more adventurous protein crystallographer. The solution of previously unknown structures described in this chapter shows how powder diffraction is already moving beyond 'demonstration' experiments and that the technique is ready to tackle genuine biological problems. It is fair to say that macromolecular powder diffraction has moved from an impossible dream to a reality, as exemplified by characterizing bulk pharmaceuticals, the molecular-replacement structure determination of the protein ponsin, the preliminary structural characterization of a Trinidadian virus which will not yield sizeable single crystals, the combination of powder-diffraction X-ray data with techniques such as cryo-electron microscopy (cryo-EM), and the combination of single-crystal data from micron-sized crystals with powder-diffraction data. Whilst it will obviously not seek to compete with single-crystal work for crystal structure analysis, macromolecular powder diffraction should be regarded as a technique that every crystallographer should know how to use. This chapter provides the necessary discussions of the theory, along with practical explanations and examples, all of which are useful for teaching. Tabulations are given of the total powder sample volume requirements in studies made so far, illustrated particularly with respect to the molecular weights of the proteins studied, where the amount required can increase significantly and/or where more detail is needed at the molecular level (Table 7.1.1); the instruments available at synchrotron sources worldwide (also Table 7.1.1); and software packages and their detailed capabilities (Table 7.1.2).

In this chapter, we cover the following:

1. methods for 'ideal powder' sample preparation;
2. synchrotron X-ray macromolecular powder diffraction (SXRPD) instrumentation options and measurements;
3. software suites commonly used;
4. a general survey of examples;
5. several highlighted case studies;
6. cases where combination with other methods, notably microcrystallography or electron microscopy (EM), is advantageous; and
7. some imaginative future prospects, including the use of electrons and X-ray lasers.

Particular emphasis is given throughout on cryo-cooling methods for protein powders for extending the sample's lifetime in the beam. Cryo-cooling techniques continually advance in order to reduce radiation-induced sample microstrains, which lead to severe peak broadening and loss of information owing to the high degree of reflection overlap. These advances are described in Section 7.1.4. Likewise, the use of the anisotropic changes in unit-cell parameters (usually evident with X-ray irradiation damage at synchrotron sources, even when cryo-cooled) allows more complete extraction of data; indeed, since peak overlap is increasingly severe at higher diffraction resolutions, this is a most important development for detailed work. Thus these two aspects of modern practice are discussed in detail (Watier *et al.*, 2009), as they are likely to be essential to practitioners facing increasingly challenging cases.

Powder diffraction is ideal for screening a large number of samples and current advances in this field are discussed in Section 7.1.5. During the last few years, there has been an evolution from single- to multiple-pattern fitting, leading to improvements in the data and resulting models, and we describe these in Section 7.1.6. Perhaps the most enticing goal for any crystallographer is to solve new structures, and Section 7.1.7 discusses the progress and prospects for powder diffraction in this area. Details of the application of the Rietveld method (Rietveld, 1969) and the use of stereochemical restraints as well as rigid bodies for the description of individual amino acids in the course of structure refinements are provided in Section 7.1.8. It is anticipated that the combination of powder diffraction with other experimental techniques, including X-ray microcrystallography, serial X-ray crystallography at free-electron lasers and electron diffraction (ED) methods will be highly advantageous, and related developments are discussed in Section 7.1.9. We end with some concluding remarks and a discussion of future prospects for the method in Section 7.1.10.

7.1.2. Sample preparation and handling

Preparation of suitable protein powder samples is considerably easier than that of high-quality single crystals. Protein powders are inherently 'perfect' for diffraction; the individual crystallites are of the right size (about 1 µm) and are almost completely strain free. Polycrystalline protein can be prepared directly by precipitation from solution, usually working at relatively high precipitant and/or protein concentrations in order to reach the precipitation zone limits (Asherie, 2004). To date, we have employed the salting-out procedure in batch mode for the preparation of several different polycrystalline protein samples, as shown in Fig. 7.1.1 (Margiolaki & Wright, 2008). The sample is preserved in an adequate amount of mother liquor or solvent to ensure that the protein powder does not dehydrate. Powders may also be prepared by simply grinding or pulverizing in their mother liquor a sufficient quantity of single crystals grown by conventional means. For example, Rotella *et al.* (2001) used a sonicator to prepare their samples, while Von Dreele hand-

Optical-microscopy images of needle-shaped crystals of the nonstructural protein 3 (nsP3) macro domain of the Mayaro virus (MAYV) grown under different conditions (Papageorgiou *et al.*, 2010).

ground metmyoglobin (Von Dreele, 1999) and Zn insulin (Von Dreele *et al.*, 2000) crystals with an agate mortar and pestle. However, the application of pressure to protein crystals may result in different crystalline phases, as demonstrated by Von Dreele and co-workers (Von Dreele *et al.*, 2000). The resulting slurry is then loaded into a glass capillary and centrifuged in order to enhance packing of the protein crystals. Excess mother liquor is removed and the capillaries are sealed with wax to prevent protein dehydration.

Our high-angular-resolution synchrotron experiments typically use a 1.0 mm-diameter borosilicate or Kapton capillary (Von Dreele, 2006) that is illuminated over 2–6 mm of its length depending on the instrument; this specimen size uses approximately 5–15 mg of protein. Much smaller capillaries can be used on diffractometers equipped with either a charge-coupled device (CCD) or an image plate (IP); a 0.3 mm capillary requires only 0.02 mg of protein for the beam size normally used on these instruments. Alternatively, a small quantity of the slurry can be placed in a standard single-crystal loop, although dehydration of the sample is quite likely unless it is flash frozen. The amount of protein required is much less than 1 mg. In order to reduce the amount of sample required and avoid protein dehydration, Watier (2011) has employed Silson silicon-nitride membranes as alternative sample holders. The membrane window consists of a square silicon-nitride membrane in a square supporting frame. For synchrotron measurements at ID31 (ESRF) we chose a window size of 3 mm × 3 mm, slightly larger than our typical beam size of 2 mm × 1 mm. The window thickness was 500 nm (the available range is from 50 nm to 1000 nm). The sample was pipetted directly on top of the window. To avoid dehydration of the protein sample, a second Silson membrane was added on top and sealed with grease. This double silicon-nitride window allows collection while spinning (as with a capillary). A different approach was also proposed by Watier (2011) in order to collect synchrotron data on the smallest possible protein sample. The sample used corresponds to the nsP3 macro domain of the Mayaro virus, which forms needle-shaped crystals grown within single ‘urchins’ as shown in Fig. 7.1.2 (Papageorgiou *et al.*, 2010). In this case, a single urchin was loaded onto a micromesh grid holder 400 µm in diameter with a 25 µm opening (MiTeGen MicroMeshes). The urchin was kept hydrated with a humidity controller (Sanchez-Weatherby *et al.*, 2009) and data were collected using an area detector at the protein crystallography beamline ID14 (ESRF). We note that this setup is ideal for observation of the dynamic response of macromolecular crystals to changes in relative humidity (Dobrianov *et al.*, 2001; Hanson *et al.*, 2003), a field of great biotechnological importance (Salunke *et al.*, 1985; Kuntz & Kauzmann, 1974; Finney, 1979; Careri *et al.*, 1980; Blake *et al.*, 1983). Considering the very low amount of material, unexpectedly good diffraction patterns were observed

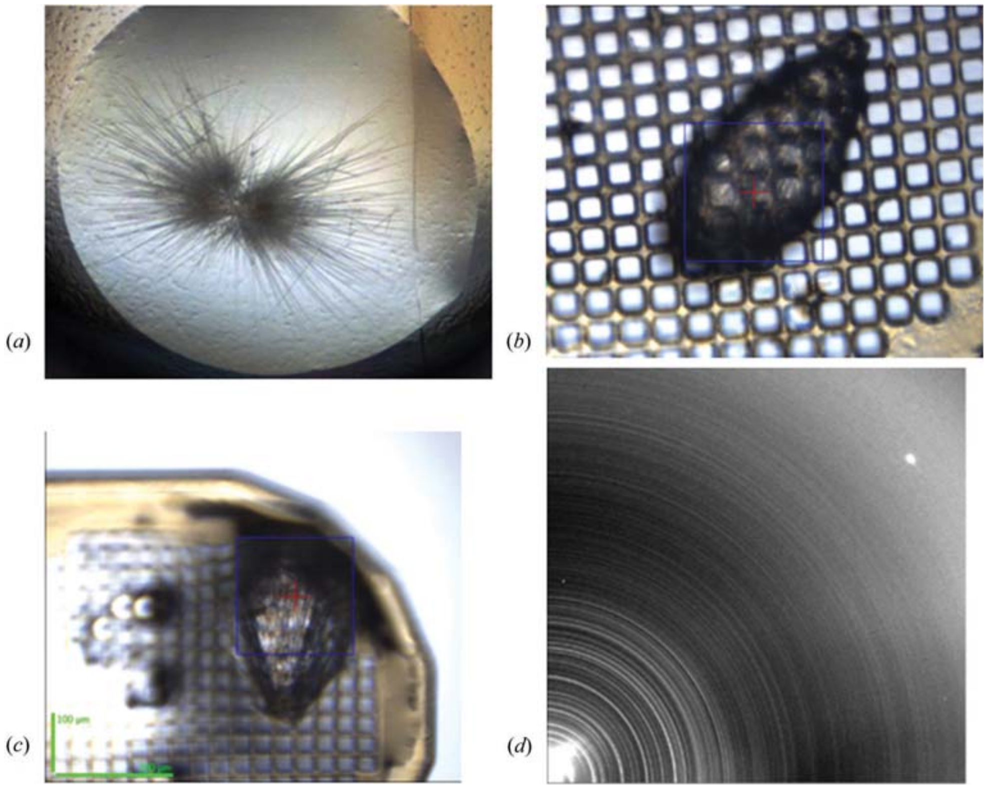

Figure 7.1.2
(*a*) A bunch of needle-shaped MAYV crystals as grown within single 'urchins'. (*b*, *c*) A single urchin was loaded onto a micromesh grid holder 400 μm in diameter with 25 μm openings (MiTeGen MicroMeshes). The urchin was kept hydrated with a humidity controller (Sanchez-Weatherby *et al.*, 2009) and (*d*) data were collected using an area detector at the protein crystallography beamline ID14 (ESRF) (Watier, 2011).

compared with the capillary-mode measurements (Fig. 7.1.2*d*) and therefore this method is considered as very promising for future protein powder experiments.

Finally, a different type of sample holder for in-house X-ray powder-diffraction (XRPD) analysis has recently been made and tested on lysozyme (Frankaer *et al.*, 2011). To collect as much signal as possible on in-house X-ray sources, the general principle behind the design is to support a thin film of protein crystallites with a relatively large surface area. The sample holder consists of a 1.0 mm-thick polycarbonate plate with a hole in it, either 4.5 or 3.0 mm in diameter, creating a sample-chamber volume of 16 or 7 μl, respectively. Metal-free polycarbonate was chosen to avoid a fluorescence signal from the sample holder. The sample is sealed by two pieces of Mylar foil, which are attached to the polycarbonate plate with either epoxy glue or double-sided adhesive tape. The use of an integrated pinhole reduced the background, and good signal-to-noise ratios were obtained from only 7 μl of sample, corresponding to approximately 2–3 mg of dry protein. The sample holder is further adaptable to X-ray absorption spectroscopy (XAS) measurements. Both XRPD and XAS at the Zn *K* edge were tested with hexameric Zn insulin.

7.1.3. Data collection

A crucial step in a protein powder experiment is the choice of the optimum instrument. While most of the early studies were limited to dedicated powder-diffraction instruments, it is becoming increasingly clear that a wider range of instrumental configurations can give additional useful information. A typical single-crystal synchrotron beamline should also give a good-quality powder pattern from a very small sample if the X-ray beam is focused at the detector surface. Once a sample is found to be microcrystalline, it is worthwhile to pursue an improved powder pattern. One of the main barriers appears to be the fact that the unit-cell volumes can be three orders of magnitude larger than those traditionally studied by powder methods. A particularly important question is the comparison of data-collection schemes with high-resolution analyser crystals on the one hand and multichannel position-sensitive detectors (one- and two-dimensional) on the other. Whereas the former configuration offers maximum angular resolution, the latter provides substantially higher data-collection rates, and therefore faster acquisition, allowing for studies of particularly radiation-sensitive systems. Data-collection strategies and data quality from different instruments of four main synchrotron sources (ESRF, APS, SPring8 and SLS) as well as laboratory instrumentation have been discussed (Margiolaki, Wright, Fitch *et al.*, 2007; Helliwell, 2012). Each instrumental configuration tested offers advantages in specific applications. While it is tempting to try to obtain the highest-angular-resolution data, a compromise is always forced upon us by the effects of radiation damage and the costs of producing large amounts of samples. In the process of screening extensive series of specimens under different conditions, the need

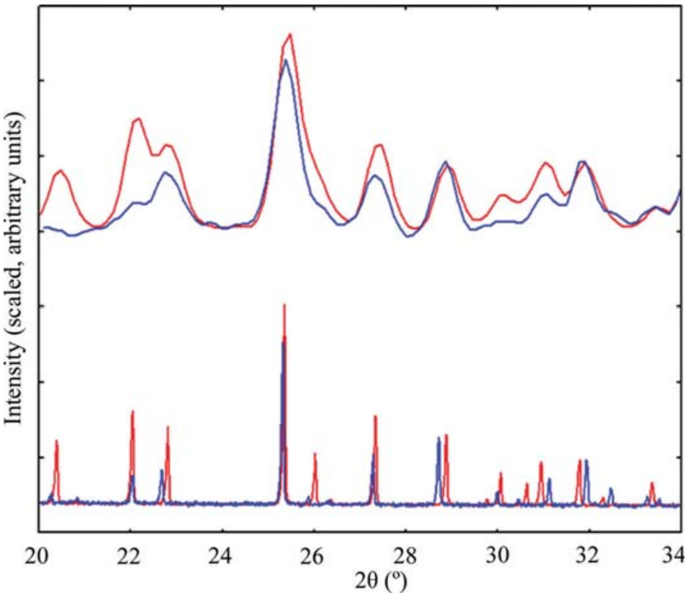

Figure 7.1.3
Low-angle region of powder-diffraction patterns from lysozyme samples. The lower and upper patterns correspond to analyser-crystal (ID31) and area-detector (BM01A) data, respectively. In these experiments, the intensities of certain low-angle reflections are modulated by varying the mean electron density of the solvent surrounding the protein molecules in the crystal *via* variations in the solvent composition. The red and blue spectra correspond, respectively, to samples soaked in solvents that have low and high electron density (Margiolaki & Wright, 2008).

Table 7.1.1
Synchrotron beamlines used for protein powder measurements and their key characteristics

Beamline	Detector type and energy range	Amount of sample required (protein precipitate)	Advantages, disadvantages and uses
ID14 – EH1 (ESRF)	Large two-dimensional detector (Quantum 210), E = 13.270 keV	1–5 µl (~1 crystallization drop)	Medium angular resolution, screening, initial indexing and phasing, fast acquisition, user friendly
ID11 (ESRF)	Two-dimensional detector (FReLoN camera), E = 25–140 keV	5–10 µl (several drops required)	Medium angular resolution, screening, ideal for tests of small amounts of samples and experimental configurations; complex to use
ID31 (ESRF)	Nine Si(111) analyser crystals each followed by a point detector [avalanche photodiode (APD) detectors], E = 5–60 keV	10–50 µl (batch crystallization is preferable as relatively large sample amounts are required)	High angular resolution, ideal for structure solution and refinement, robotic sample changer available, online data viewing and treatment software, user friendly, extensive use for protein powder diffraction
BM01B (ESRF)	Six Si(111) analyser crystals each followed by a point detector (NaI scintillation counters), E = 4–70 keV	10–50 µl (batch crystallization is preferable as relatively large sample amounts are required)	High angular resolution, structure solution and refinement
MS – X04SA (SLS)	Configuration 1: Five Si(111) analyser crystals each followed by a point-detector [NaI(Tl) scintillators–photomultipliers] Configuration 2: Modular (each module covering *ca.* 5° in 2θ) one-dimensional solid-state Si microstrip detector (MYTHEN II) covering 120° in 2θ E = 5–40 keV	10–50 µl 5–10 µl	High angular resolution (down to 0.002° in 2θ), ideal for structure solution and refinement, anomalous scattering Very fast acquisition time (down to 100 ms in continuous mode, down to 100 µs pump-and-probe mode), angular resolution dominated by capillary diameter (*ca.* 0.02° with a 0.3 mm capillary), ideal for time-resolved, dose-controlled structural analyses, robotic sample changer available.
BL40XU (SPring8)	Large Guinier-type camera, E = 8–17 keV	1–5 µl	High angular resolution, 1 m path length, structure solution and refinement, very fast data collection
17-BM (APS)	Two-dimensional detector (MAR345 and GE) offset vertically, E = 20 keV	1–5 µl	30 s data collection, medium angular resolution to ~2 Å d-spacing resolution
11-BM (APS)	12 Si(111) analyser crystals each followed by an $LaCl_3$ point detector, E = 12–36 keV	1–5 µl	High angular resolution, ideal for structure solution and refinement, robotic sample changer available

to collect patterns rapidly from small samples is more important than obtaining data suitable for structure refinement. The unit-cell parameters can normally be refined very precisely from a relatively small (<50) number of low-angle peaks. The use of a lower-angular-resolution instrument allows construction of phase diagrams and checking for ligand or heavy-atom binding to be carried out rapidly using small samples. When particularly interesting samples are identified during screening and a structure solution or refinement is to be attempted, it is of course vital to obtain the best possible data to increase the chances of success for the whole process. Here the analyser-crystal beamlines offer unparalleled instrumental resolution, which is very attractive in reducing the peak overlap (Fig. 7.1.3). In comparison, multichannel position-sensitive detectors, particularly those designed for larger unit cells, offer dramatically improved counting statistics. Ideally, both types of data set should be available in a combined refinement in order to exploit the advantages of each. The special characteristics of protein powders require development of instrumentation to take real advantage of the inherent sharpness of the diffraction patterns, while at the same time avoiding radiation-damage effects. From one point of view, this could be achieved using high-spatial-resolution two-dimensional area detectors designed to cover only the most useful part of the powder pattern (the low-2θ region) and by increasing the solid-angle coverage with increasing 2θ to give the best possible statistics. Table 7.1.1 lists the synchrotron beamlines used for such studies and their individual characteristics.

7.1.4. Cryo-cooling protein powder samples and microstructural effects

In a powder experiment, we sample a large number of very small crystals and the specimen will still be a powder even if some of the crystallites are broken (the typical size of the crystallites is approximately 0.1–1 µm). This has made powder methods extremely useful for the study of phase transitions and other phenomena that can ruin a fragile single crystal. If diffraction peaks are observed that are broader than the instrumental resolution, they can give some information about the microstructure of the sample. When there is a spread of cell parameters in the sample, a 'microstrain' broadening occurs and this has a larger effect at higher scattering angles. Assuming a Gaussian description of the diffraction peak widths parameterized *versus* 2θ as

$$\mathrm{FWHM}^2 = U\tan^2\theta + P/\cos^2\theta,$$

we gain the advantage that the parameters U and P can easily be related to the microstructure of the material [Larsen & Von

Dreele (2004), *GSAS* manual]. Strain broadening in real space gives $\Delta d/d$ as a constant, which can be related to the U parameter *via*

$$\text{strain} = \frac{\pi}{18000}[(8\ln 2)(U - U_{\rm i})]^{1/2}\%,$$

where $U_{\rm i}$ is the instrumental contribution. For particle-size broadening effects, the relationship is

$$\text{size} = \frac{18000K\lambda}{\pi(8\ln 2)^{1/2}P}\ \text{nm}.$$

When measured at room temperature, many proteins give diffraction peaks where the widths are limited only by the instrumental resolution. This indicates that the samples are extremely homogeneous, with all crystallites having the same unit-cell parameters. The truncation of the crystal lattice by a very small crystallite size also leads to a peak broadening which is similar over all of reciprocal space and is normally significant for crystallite sizes below about 1 µm. For structural refinements, the microstrain/size peak broadening increases at higher resolution (scattering angle) where the peak overlap is already more severe. Owing to the soft nature of the materials, the size broadening is often negligible. Crystallite sizes can be in the µm range so particle-size effects are often not pronounced. However, poor crystallinity, chemical inhomogeneity and changes induced by cryo-cooling often lead to peak broadening.

A typical protein powder sample loaded into a borosilicate capillary and mounted on the ID31 ESRF beamline (Fitch, 2004) at room temperature often cannot withstand more than two minutes exposure time owing to radiation damage. Thus, samples are translated periodically in order to expose a fresh part of the sample to the X-ray beam. When subsequent scans are collected from the same part of sample, radiation-damage effects are apparent in the observed gradual loss of peak intensities, peak shifts associated with alteration of lattice dimensions and an increase of the peak widths owing to the gradual loss of crystallinity. The suppression of radiation damage by cryo-cooling (Rodgers, 1997, 2001; Garman & Schneider, 1997) has meant that nowadays the majority of protein single-crystal structures are determined at low temperatures. For powder experiments, it is important to preserve sharp diffraction peaks and minimize peak overlaps; however, it is also useful to suppress radiation damage by cryo-cooling.

In an attempt to explore radiation damage, we initially investigated the freezing processes occurring in turkey egg-white lysozyme (TEWL) by collecting data while cooling and warming a powder sample (Margiolaki *et al.*, 2004, 2005). A phase transition in the protein structure is accompanied by freezing of the mother liquor, and leads to a broadening of the powder peaks.

In that particular case, the 'microstrain'-related peak-broadening parameter (%) was in agreement with the bulk overall contraction of the unit cell during freezing. Generating two-dimensional Fourier maps of the structure projected along the c axis gives a more direct view of the changes occurring upon freezing. Fig. 7.1.4 shows the Fourier map, which illustrates that the changes in intensity can be accounted for by a smoothing out of the electron density, which makes the apparent channel diameter seem larger. A more reasonable hypothesis for the contraction of the unit cell is that the formation of an ice phase in the bulk solvent leads to a rapid increase in the osmotic potential of the crystallization buffer. It is conceivable that this would lead to transport of liquid water out of the crystallites and would be manifested in a rapid contraction of the solvent channels and, by extension, the unit cell. While this explains the contraction, the changes in peak intensities are difficult to predict under those circumstances.

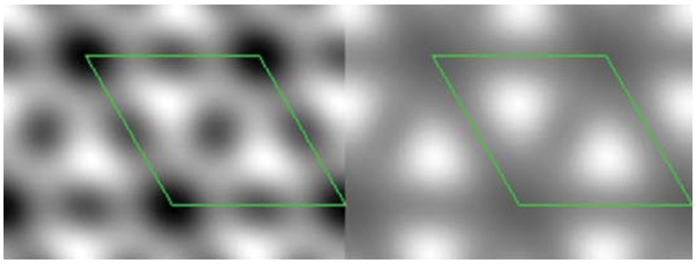

Figure 7.1.4
Projections of the electron density in the *ab* plane for TEWL at room temperature (left) and low temperature (right). The maps are constructed from the three reflections 100, 110 and 200, assuming that the phase angles do not change on passing through the freezing transition. The dark and light areas correspond to low and high electron density, respectively (Margiolaki *et al.*, 2004, 2005).

In order to find an optimized approach to cryo-cooling of powder samples, we have systematically varied the cryoprotectant type and concentration (Jenner *et al.*, 2007). With hen egg-white lysozyme (HEWL), it was shown that the unit-cell parameters of the microcrystals at low temperature are strongly affected by the addition of cryoprotectants. The changes in cell parameters were anisotropic and depended on the type of cryoprotectant molecule used. Also, the amount of induced peak broadening was found to be proportional to the change in unit-cell parameters caused by freezing; when there is less peak broadening, the unit cell was closer to the room-temperature cell. In all of these cases, the powder diagrams could be well accounted for by considering only a 'microstrain'-related peak-broadening term, meaning that the peak broadening arises mainly from having a distribution of unit-cell dimensions in the sample. Particle-size broadening effects were negligible in comparison. The increased sample size and use of a capillary to contain the powder sample means that the cooling rates are significantly lower for powders compared with single crystals in loops, and some challenges remain in finding ways to optimally cryo-cool microcrystalline samples. Moreover, in the case of HEWL, Rietveld analysis (Rietveld, 1969) showed significant differences compared with the room-temperature structure, with well defined regions of electron density being found that can be explained by bound cryoprotectant agent molecules (PEG 400) as shown in Fig. 7.1.5 (Margiolaki *et al.*, unpublished results).

Recently, a more efficient approach for cryo-cooling protein powders has been developed by our team. In this case, Kapton (polyimide) tubes are employed instead of borosilicate ones. It is well known that Kapton's high thermal conductivity (0.10 W m^{-1} K^{-1}) makes it ideal for use in dissipating and managing heat in electronic assemblies, and it is less fragile than glass (Von Dreele, 2006). Kapton tubes with an internal diameter of 1.0 mm (with a wall thickness of 0.025 mm) are usually selected. The optimum cryoprotecting agent and its concentration are protein dependent and are usually identified on a trial-and-error basis. The protein solution is then mixed with a relatively high concentration of the optimum cryoprotectant. The mixture is then transferred into the tube, which is cryo-cooled first using liquid nitrogen and later on, during data collection, by a nitrogen cryostream. In order to avoid formation of crystalline ice, rapid flash freezing of the sample is necessary, and is often unsuccessful. This problem has been partially solved by further reduction of the sample volume *via* insertion of a thinner tube

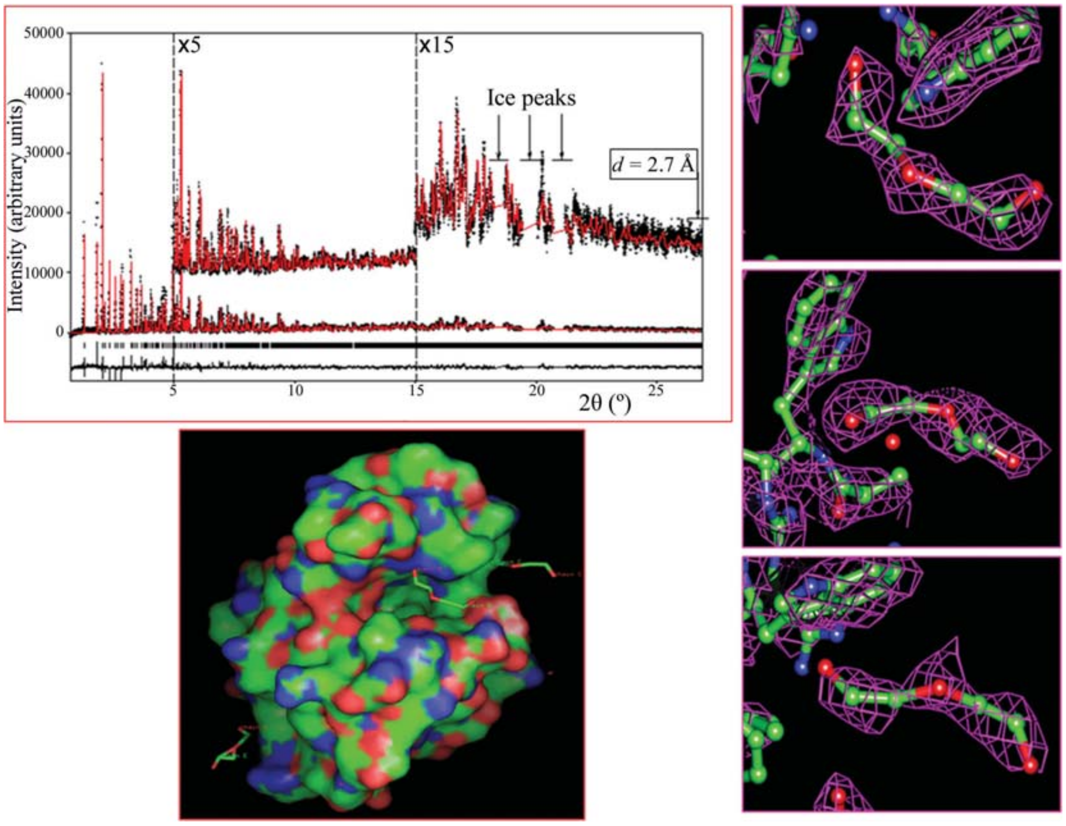

Figure 7.1.5

Upper left panel: The Rietveld fit for tetragonal HEWL at 100 K with a mixture of PEG 400 and methanol added for cryoprotection [λ = 1.250845 (23) Å, ID31, ESRF, *GSAS*: space group: $P4_32_12$, a = 78.31382 (6), c = 36.8870 (7) Å, $R_{\rm wp}$ = 6.74%, $R(F^2)$ = 9.66%]. Right panel: Perspective views of selected regions around three out of the four PEG chains of the total omit map at 2.7 Å resolution with the contour level at 1σ. Lower left panel: The refined molecular conformation of HEWL illustrated as a surface. The four additional PEG molecules identified to be bound on HEWL at 100 K are shown as cylinders.

(inner diameter 0.8 mm) inside the original one. This way, the resulting cylindrical annulus of the sample volume is reduced by a factor of three, allowing for an additional time delay in the cooling rate of the sample. As a result, faster and more uniform cooling can be obtained. This protocol led to the successful data collection for selected human insulin polymorphs (T3R3, T6) at 100 K to a d-spacing resolution limit of approximately 2.6 Å. The data resolution of the same insulin polymorphs at room temperature was approximately 3.5–4 Å. This demonstrates the substantial improvement of data quality at cryo-cooled conditions owing to the decrease of the atomic thermal motion and potential disorder of specific amino-acid regions. Electron-density maps computed from the measured structure factors and partially known structural models available from the Protein Data Bank (PDB; Berman *et al.*, 2003) (codes: 1fub, 1mso) displayed quality usually obtained from single-crystal measurements (Watier, 2011).

7.1.5. Crystal screening

Protein structure determination by X-ray crystallography is dependent on obtaining a good quality protein crystal suitable for diffraction data collection. Owing to this requirement, protein crystallization represents a key step in protein structure determination. Typical protein crystallization practice involves parallel setup and monitoring of a considerable number of individual protein crystallization experiments (Pusey *et al.*, 2005; Newman, 2011; Skarina *et al.*, 2014). Powder diffraction has been exploited as a technique for fingerprinting different crystalline substances and allows rapid phase identification and quantification of mixtures. High-resolution powder instrumentation is designed to obtain the sharpest possible peaks in reciprocal space and also to determine accurate peak positions. These features are complementary to area-detector single-crystal experiments, where the aim is normally to measure integrated intensities of diffraction peaks at the highest possible scattering angles in order to improve the direct-space resolution in an electron-density map. By exploiting the excellent reciprocal-space resolution of powder instruments, a variety of complementary studies can be carried out, studies which are typically more difficult to do with single crystals that are usually grown under a very specific set of conditions. Powder samples contain many millions of individual crystallites and give information about the bulk properties of a material; there is no question of whether a particular crystallite is representative of the whole sample. The first high-throughput demonstration study corresponded to the observation of the effect of pH and crystallization temperature on the tetragonal crystal form of HEWL (Basso *et al.*, 2005). We made accurate measurements of the evolution of the lattice parameters with pH, which is illustrated by the smooth anisotropic shifts in the peak positions in Fig. 7.1.6. The reproducibility of these results and the precision of the powder-diffraction data were verified by carrying out crystallization experiments at both 277 K and room temperature, where similar behaviour was observed.

Wherever microcrystalline proteins come into use as biomaterials or medicines, there will be an increasingly important role for powder diffraction to play. There are many benefits to using a crystalline form of an already known drug: it can allow better control over the release rate into the system by an optimization of the crystallite size and polymorphism, and it should also offer an extended shelf-life and a reduction in production costs (Yang *et al.*, 2003; Basu *et al.*, 2004; Havelund, 2009; Brader & Sukumar, 2005; Rabinow, 2004; Aguiar *et al.*, 1967; Bauer *et al.*, 2001). Microcrystalline forms of drugs tend to be slower acting, as the crystallites must dissolve before acting. Crystallite size and polymorphism both affect dissolution rates, and so they are important factors in understanding and characterizing formulations.

Our studies on microcrystalline human insulin (HI) and urate oxidase/rasburicase (Uox) (Collings *et al.*, 2010; Fili *et al.*, 2015; Karavassili *et al.*, 2017) suspensions using the powder-diffraction method have revealed a high degree of polymorphism upon variation of their physico-chemical environment (pH, ligand binding *etc.*). Even more important was our discovery of two new biologically active insulin–phenol complexes, which were later characterized *via* single-crystal methods (Norrman & Schluckebier, 2007). The effects of the ligands phenol and resorcinol on the crystallization of HI have been investigated as a function of pH. Powder-diffraction data were used to characterize several distinct polymorphic forms. A previously unknown polymorph with monoclinic symmetry ($P2_1$) was identified for both types of ligand with similar characteristics [the unit-cell parameters for the insulin–resorcinol complex were a = 114.0228 (8), b = 335.43 (3), c = 49.211 (6) Å, β = 101.531 (8)°] (Karavassili *et al.*, 2012). In a more recent study, HI was co-crystallized with two distinct phenolic derivatives, the organic ligands *meta*-cresol (*m*-cresol) and 4-nitrophenol (Valmas *et al.*, 2015). The formation of polycrystalline precipitates was then followed by means of structural characterization of the individual specimens in terms of unit-cell symmetry and dimensions employing both laboratory and synchrotron instruments. In both cases of ligands, two different polymorphs were identified, the first adopting the known trigonal symmetry ($R3$ space group) at higher pH values and a second of monoclinic symmetry (space group $P2_1$) with lattice parameters a = 87.4282 (5), b = 70.5020 (3), c = 48.3180 (4) Å, β = 106.8958 (4)°, the latter to our knowledge never observed before.

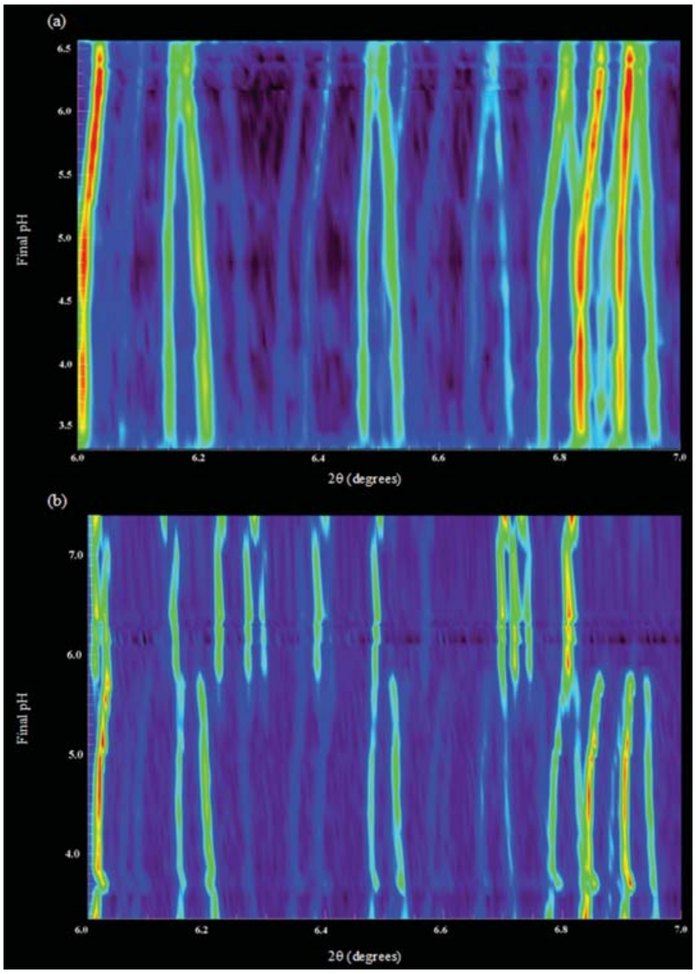

Figure 7.1.6
Colour representation of ID31 powder-diffraction data from the pH variation experiment, from pH 6.56 to 3.33, of HEWL crystallized at 277 K (*a*) and room temperature (*b*). At low temperature the tetragonal phase is favoured and a smooth anisotropic shift in the peak position is apparent (Basso *et al.*, 2005).

We note that the two new monoclinic polymorphs appear only at acidic environment (pH range: 5–6.3) using ligands such as phenol and specific derivatives such as *m*-cresol and 4-nitrophenol. On the other hand, the already known $P2_1$ phase, with lattice parameters a = 61.247, b = 61.739, c = 47.467 Å, β = 111.32° (PDB code: 1ev6), was previously detected at pH ~ 7 when insulin was co-crystallized with *m*-cresol, resorcinol (Smith *et al.*, 2000) or phenol (Derewenda *et al.*, 1989). The comparison between the known and novel isosymmetrical monoclinic forms, indicates, besides the larger unit-cell parameters, unusual crystal packing motifs for the new forms. The structurally known HI monoclinic polymorph (Smith *et al.*, 2000; PDB code 1ev6), consists of six molecules per asymmetric unit and 48% solvent content. According to the Matthews coefficient calculation (Matthews, 1968; Kantardjieff & Rupp, 2003), the $P2_1$ polymorph described by Valmas *et al.* contains 12 molecules per asymmetric unit and 39% solvent content (Matthews coefficient = 2.03 $\text{Å}^3\,\text{Da}^{-1}$). This large difference reveals a much denser crystal packing in the case of the novel monoclinic phase, which could be of great pharmacological importance. Structure solution of the novel polymorphs is currently in progress.

In the case of Uox, a key protein component of existing drugs (*i.e.* Fasturtec) that helps the body to eliminate uric acid (McGrath & Walsh, 2005; Wu *et al.*, 1992; Retailleau *et al.*, 2004, 2005), a previously unknown, biologically active polymorph was discovered when crystallization was performed in the absence of any chemical additives. Part of the current research within our group is devoted to the structural characterization of an extensive series of insulin–ligand complexes and Uox polymorphs prepared at different crystallization conditions (pH, ionic strength, crystallization agent) which are potential drug targets. Fig. 7.1.7 illustrates the tetrameric form of Uox co-crystallized with its inhibitor 8-azaxanthine (PDB code: 1r51) (Retailleau *et al.*, 2004).

There is a noticeable increase in the variety of protein powder data appearing in the literature for biological macromolecules systematically exhibiting difficulties in crystal growth. These include insect virus polyhedra, membrane proteins and amyloid-forming peptides. Polyhedra are naturally occurring protein crystals which form an armour coating around certain viruses. The crystals are extremely stable, shielding the virus particles from environmental damage and enabling them to survive in harsh environments over extended periods of time. Until a few years ago, the detailed atomic structures of the polyhedra remained unknown, in part because of the small size of the crystals. However, there have been several attempts at identifying the crystalline phases of different virus families including polyhedra (Anduleit *et al.*, 2005; Watier, 2011). Complete structural models have been subsequently solved *via* single-crystal diffraction by microcrystals with sizes smaller than 10 μm (Coulibaly *et al.*, 2007; Ji *et al.*, 2010; Evans *et al.*, 2011). Several data sets for

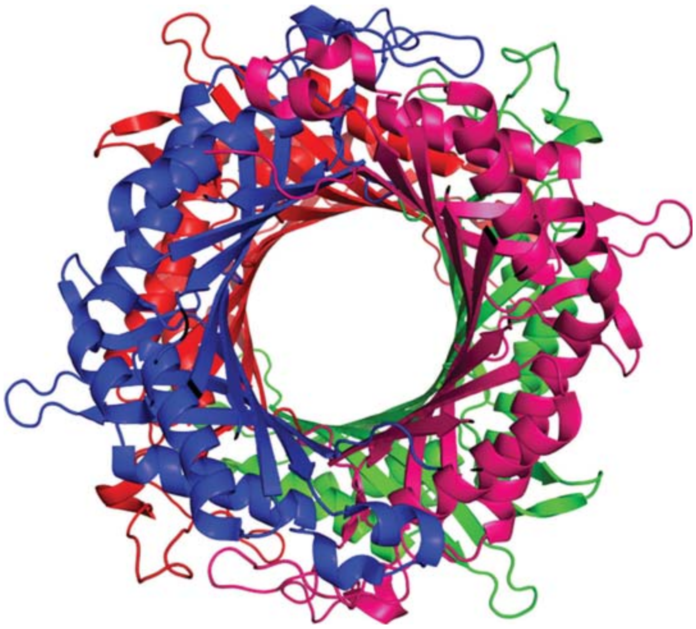

Figure 7.1.7
The tetrameric form of urate oxidase (Uox) co-crystallized with its inhibitor 8-azaxanthine (PDB code: 1r51, space group: $I222$, a = 81.30, b = 96.30, c = 105.60 Å) (Retailleau *et al.*, 2004; Collings *et al.*, 2010). The different colours correspond to four symmetry-related protein chains.

membrane proteins have been collected at various synchrotron sources and currently there are two published articles on the bacteriorhodopsin (bR) molecule from two-dimensional purple membrane crystals presenting mainly methodological developments for low-resolution phasing (Oka *et al.*, 2006; Dilanian *et al.*, 2011). Finally, there are several powder-diffraction studies of amyloid-forming peptides, mainly presenting identification of distinct crystalline phases (Balbirnie *et al.*, 2001; Bond *et al.*, 2003; Diaz-Avalos *et al.*, 2003; Inouye & Kirschner, 2006).

The possibility of using powder-diffraction data on microcrystalline protein samples for detection of ligands in protein–ligand complexes was illustrated by the studies of HEWL complexes with *N*-acetylglucosamine (NAG*n*, *n* = 1–6) oligosaccharides (Von Dreele, 2001, 2005). All of the protein powder-diffraction patterns in these studies showed extremely sharp Bragg peaks consistent with crystallites greater than 1 µm in size; the peaks were also devoid of line-broadening defects. The location of each NAG*n* could be found from difference-Fourier maps generated from structure factors extracted during preliminary Rietveld refinements. Full NAG*n*–protein structures were subjected to combined Rietveld and stereochemical restraint refinements and revealed binding modes for NAG*n* that depended on the length of the NAG oligosaccharide (Fig. 7.1.8). The series of refined powder structures is available in the Protein Data Bank *via* access codes 1ja2, 1ja4, 1ja6, 1ja7, 1sf4, 1sf6, 1sf7, 1sfb and 1sfg. These studies showed that powder diagrams can give interpretable electron-density maps for protein samples and showed unambiguously that a powder sample can be sufficient for structural analysis.

7.1.6. Improvements in data quality *via* the use of multiple profiles

Powder data suffer from peak overlap. If this problem can somehow be circumvented (or at least reduced), we should be able to solve and refine larger structures more easily using powder methods. Changing the pattern of peak overlaps and collecting multiple data sets is one strategy for reducing the overlap problem. Varying the temperature of the sample for low-symmetry unit cells often leads to anisotropic thermal expansion, and therefore allows overlapped peaks to be untangled (Shankland *et al.*, 1997; Brunelli *et al.*, 2003). Similarly, if a sample can be prepared with a significant degree of preferred orientation, then overlapped peaks will have different intensities depending on the orientation of the sample (Dahms & Bunge, 1986; Bunge *et al.*, 1989; Cerny, 1996; Baerlocher *et al.*, 2004). Combining multiple data sets where either the cell parameters or the preferred orientation are different gives some information about the way in which the overlapped peaks should be partitioned. In order to benefit from anisotropic changes in unit-cell parameters for intensity extractions, the *PRODD* refinement program (Wright & Forsyth, 2000; Wright, 2004) was modified to allow a different set of unit-cell parameters to be used for each pattern in a multi-pattern Pawley fit (Pawley, 1981). A single list of Bragg-peak intensities is fitted to the profiles while an overall isotropic displacement coefficient and scale factor for each profile account for the bulk of the differences between the patterns. A Pawley refinement of myoglobin using high-resolution synchrotron data (λ = 0.413465 Å, BM16, ESRF) and *PRODD* illustrated the applicability of the method in cases of significant complexity and severe peak overlap (Wright, 2004). The integrated intensities that are extracted from the multi-pattern powder data are a considerable improvement over those that come from a single data set (Besnard *et al.*, 2007; Margiolaki, Wright, Fitch *et al.*, 2007) and are then useful for attempts at structure solution using single-crystal software packages. Care must be taken to ensure that the reflection intensities from the powder diagrams are corrected properly for Lorentz and multiplicity factors, and also that sensible error estimates are supplied. Error estimates on the extracted intensities are in principle difficult to determine properly.

Several studies demonstrate that the most significant improvements arise from the use of multiple data sets during intensity extraction (Besnard *et al.*, 2007) and/or structure refinements (Von Dreele, 2007; Basso *et al.*, 2005; Margiolaki, Wright, Wilmanns *et al.*, 2007). The unit-cell parameters are perturbed to alter the pattern of peak overlaps in the different patterns and reduce the overlap problem. Perutz (1954) used

perturbations of the unit-cell parameters with single-crystal data in an early attempt to solve the phase problem by oversampling of reciprocal space. This approach was apparently abandoned owing to the development of other, simpler, phasing methods. Thus far, we have not attempted to exploit the intensity differences which come with the unit-cell changes for phasing, although in theory the oversampling method may still be applicable. Table 7.1.2 lists the software packages that allow extraction of reflection intensities including analysis of multiple profiles and calculation of error estimates.

7.1.7. Structure solution

If powder data contain enough information to refine the structure of a small protein, then it follows that the structure might also be solved from the same data. We are choosing an inclusive definition of 'solving' a protein structure in this context. The use of stereochemical restraints and introduction of prior knowledge, such as the amino-acid sequence, will be used to fill in missing information at high resolution. The first step in an analysis is the identification of cell dimensions and crystal symmetry. With high-resolution data, identification of cell dimensions is often straightforward. However, with poorer data, and particularly when the sample contains more than one crystalline phase, indexing can become a serious bottleneck. If the data appear reasonable and indexing does fail, then the most likely cause is the existence of more than one phase. Software has been developed for detecting the existence of secondary phases (David & Shankland, 2008). Whereas the inability to determine the correct unit cell makes structure solution impossible, some uncertainty in the correct space group is not an intractable problem, as each potential space group may be tested separately. Possible space groups are determined by examining diffraction patterns for systematically absent reflections. Severe ambiguities related to the correct space group may arise from the overlap of diffraction peaks, either accidental or as an unavoidable consequence of the crystal symmetry (*i.e.* the exact overlap of non-equivalent reflections in certain high-symmetry Laue groups). Determining absences for long *d*-spacing reflections is normally straightforward, but at shorter *d*-spacings reflection overlap makes it a much more subjective process. Choosing the space group with the fewest number of contributing reflections is a good pragmatic approach to resolving this problem. In the case of proteins, considerable help in space-group selection comes from their chiral nature, which limits the allowed space groups, and the well known frequency distribution of space groups (Andersson & Hovmöller, 2000). Some space groups can be eliminated from the beginning, since they require symmetries known to be absent in the molecule itself. For example, space groups with reflection or inversion symmetries cannot be observed for chiral molecules; thus, only 65 space groups of the possible 230 are allowed for protein molecules, which are almost always chiral. One of the most puzzling observations in protein crystallography is that the various space-group symmetries occur with striking non-uniformity. Earlier studies have shown that the observed frequencies for both two- and three-dimensional crystals can be explained by an entropic model. Under a requirement for connectivity, the favoured space groups are simply less restrictive than others, in that they allow the molecules more rigid-body degrees of freedom and can therefore be realized in a greater number of ways (Wukovitz & Yeates, 1995). In addition, over the past decade probabilistic approaches to space-group determination have been developed that remove the need for subjective judgements about the presence or absence of classes of reflections throughout the pattern (Markvardsen *et al.*, 2001; Altomare *et al.*, 2004). Knowing the most likely extinction symbol, it is usually a straightforward matter to pick the most likely space group. As such, these methods are particularly useful when dealing with systems of orthorhombic symmetry or higher, where the number of possible space groups (and settings) is relatively large.

Powder data can certainly be used to uncover new structural information at low or even modest resolution, and we expect to see this becoming a more common approach in the future. As water molecules have been seen in at least two refinements already (Margiolaki, Wright, Wilmanns *et al.*, 2007; Von Dreele, 2007), we can be confident that powder data will be sufficient to unravel new structural information.

7.1.7.1. *Molecular replacement*

In the molecular-replacement method (Rossmann, 1990), a model for a protein molecule is proposed based on known structures of proteins that have similar amino-acid sequences. This model is then oriented and positioned in the unit cell to match the experimental data for the unknown structure. In this era of structural genomics (Stevens *et al.*, 2001), the quality of the search models is expected to improve dramatically, so that molecular replacement using a powder diagram may be sufficient to confirm that a new protein is indeed similar to one that is previously known. Proteins are often found in a variety of different organisms with very similar amino-acid sequences, or are expressed with a few modified residues to investigate the effects these changes have on the protein. There are only six degrees of freedom to be determined per molecule in solving a structure by molecular replacement. The first three give the orientation and the second three give the position of the molecule with respect to the symmetry elements of the space group. Relatively low resolution data can often be used for molecular-replacement problems. A resolution of 6 Å can be sufficient and a cutoff of 3 Å is often applied. The solution of the structure of T3R3 insulin (Von Dreele *et al.*, 2000) was the first example of the molecular-replacement method using powder data (Fig. 7.1.9). In our own laboratory, we successfully used *MOLREP* (Vagin & Teplyakov, 1997) together with powder data for a variety of small proteins (consisting of 50–150 amino-acid residues). Integrated

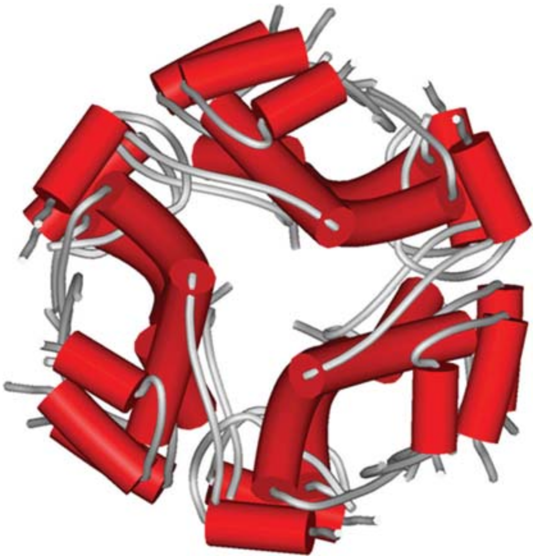

Figure 7.1.9

intensities are extracted (Wright, 2004) from the powder profile and then treated as if they came from a single crystal, ignoring the overlap problem. Fortunately, the molecular-replacement method tolerates errors in the input diffraction data as if they were due to errors in the model for the structure. In the cases of turkey (Margiolaki *et al.*, 2004, 2005) and hen (Basso *et al.*, 2005) egg-white lysozymes, there was a clear distinction between the best structure proposed by *MOLREP* and the second best, and in both cases the best structures were the correct positions and orientations for the molecule in the unit cell. After determining the position and orientation of a model for the protein molecule in the unit cell, it is of critical importance to be able to go through the structure and identify the regions that are different in the new protein compared with the initial model. A more recent example is the structure solution of the second SH3 domain (SH3.2) of ponsin *via* molecular replacement. The high quality of the extracted intensities from the measured profiles led to the unique determination of an unknown 544-atom protein structure (70 amino-acid residues) from powder data. The search model had 38% amino-acid sequence identity and was still sufficient for molecular replacement and model building based on electron-density maps calculated at 2.3 Å diffraction resolution. Fig. 7.1.10 illustrates the structure of the SH3.2 domain derived from powder diffraction (Margiolaki, Wright, Wilmanns *et al.*, 2007). Another example of a molecular-replacement-style approach is the use of phase angles or direct structural information from another technique, combined with data collected using powder-diffraction methods. Oka *et al.* (2006) have investigated the structure of purple membranes, which comprise two-dimensional crystals of bacteriorhodopsin trimers. They collected high-resolution synchrotron powder-diffraction data using a 1 m-path-length Guinier-type camera at beamline BL40B2 at SPring-8. By combining extracted intensities up to a resolution of 4.2 Å with phases from cryo-electron microscopy, they were able to produce an electron-density map. The data from the synchrotron improved the resolution for purple membrane compared with that attained previously with laboratory X-rays (intensities extracted up to ~7 Å) and opens up the possibility of studying these systems under a wider range of conditions. Moreover, Dilanian *et al.* (2011) proposed a novel method for treating highly overlapped reflections. They applied it to the structure of the bacteriorhodopsin (bR) molecule to a resolution of 7 Å using only powder-diffraction data obtained from two-dimensional purple membrane (PM) crystals.

Recently, we have extended our studies on the 160 amino-acid nsP3 protein macro domain of the Mayaro virus (MAYV), an emerging virus of South American tropical regions, by means of powder diffraction on microcrystalline precipitants. These results correspond to the first structural data existing in the literature since 1954 when the virus was isolated in Trinidad (Anderson *et al.*, 1957; Causey & Maroja, 1957). Comparison with known structures of sequence-homologous Chikungunya virus (CHIKV) macro domains (Malet *et al.*, 2009) indicate that MAYV adopts a trigonal/hexagonal structure associated with a looser molecular packing. The cell dimensions of MAYV are significantly altered in comparison to CHIKV and the unit cell is composed of six molecules and 58% solvent. Structure solution *via* the molecular-replacement technique and refinement of MAYV are currently in progress (Papageorgiou *et al.*, 2010).

Among hundreds of virus recombinant proteins isolated every year, considered as potential antivirus targets, several did not produce sizeable single crystals required for classical single-crystal X-ray diffraction studies. However, some of them produced microcrystals ideal for XRPD measurements. In certain cases, we have performed preliminary measurements validating the feasibility of the aforementioned approach especially concerning protease 3C of Coxsackie virus B3 (COXVB3) and Dengue virus (DENV) non-structural protein 5 (NS5) methyltransferase domain. In both cases, preliminary crystallization screens produced microcrystals and XRPD data were sufficient for polymorph identification for a specific crystallization condition (Fili *et al.*, 2016; Valmas *et al.*, 2017).

Finally, Doebbler & Von Dreele (2009) have shown that macromolecular structures can be solved *via* molecular replacement from powder-diffraction data collected not only on multi-analyser diffractometers but also on image plates. Diffraction peaks recorded on image plates are generally broader in line-width than those collected using an array of crystal-analyser detectors, but the image-plate data often allow the use of powder data to lower *d*-spacings. Owing to the high incidence

of reflection-intensity overlaps in powder patterns (which is especially evident for larger biological macromolecules), a multiple-diffraction-pattern Pawley refinement is necessary in order to distinguish intensity peaks. Von Dreele utilized various salt concentrations to produce small lattice distortions, which resulted in shifts of Bragg-peak positions in a suite of five powder-diffraction patterns. Using reflection structure-factor amplitudes obtained from this combined refinement, the structure of hen egg-white lysozyme was determined by molecular replacement using the 60% identical human lysozyme (PDB code 1lz1) as the search model. This work also expanded upon previous work by presenting a full-scale multi-species analysis combined with an investigation of the sensitivity with regard to discrimination between incorrect protein fold types. To test the limits of this technique, extension to higher-molecular-weight biological macromolecules is ongoing.

7.1.7.2. *The isomorphous-replacement method*

When there is no starting model available for a protein molecule, then we face the crystallographic phase problem. The isomorphous-replacement method (Perutz, 1956) determines the phases of X-ray reflections by comparing data from a series of crystals that contain different additive heavy atoms. This method was already in common use (prior to the application to proteins) for the determination of organic structures by comparing crystalline salts with differing cations or anions. The first application to proteins (Green *et al.*, 1954) was used to determine the signs of centric reflections in haemoglobin. In order to use the isomorphous-replacement method, one needs to collect data for a protein with and without the added heavy atom and to be able to measure and interpret the differences in the data due to the added atoms. Difficulties arise when the addition of the heavy atom perturbs the structure, leading to non-isomorphism and differences that can no longer be simply interpreted by a few atoms. With powder data, we can determine whether or not a particular heavy atom has formed a derivative by comparing the unit-cell parameters, which are normally perturbed by the addition of a heavy atom. In the case of a gadolinium derivative of hen egg-white lysozyme (HEWL) (Wright *et al.*, 2007), we prepared derivatives using different concentrations of Gd and also different pH values in order to alleviate the peak-overlap problem. Extracted intensities were then used to solve for the atomic positions of the Gd atoms using *SHELXD* (Usón & Sheldrick, 1999) and then refinement of the heavy-atom substructure and phasing were carried out using *Sharp* (La Fortelle & Bricogne, 1997). Similarly, in the case of a uranium derivative of porcine pancreatic elastase (PPE), a 240-amino-acid residue protein of 25.9 KDa molecular weight (Besnard *et al.*, 2007), the peak-overlap problem was reduced by comparing data sets that had been exposed to the X-ray beam for different amounts of time. The gradual changes in unit-cell parameters due to radiation damage changed the pattern of peak overlaps sufficiently so as to successfully deconvolute the overlapping diffraction peaks. The U atom is clearly visible in a difference Patterson map from native and derivative data sets, and phasing using *Sharp* proceeds to give a solvent mask which clearly and correctly delineated the protein and solvent regions (Wright *et al.*, 2007, 2008*a*,*b*). Recently, two heavy-atom derivatives of tetragonal HEWL (a gadolinium derivative and a holmium derivative) were crystallized at room temperature. Using synchrotron radiation, high-quality powder patterns were collected in which pH-induced anisotropic lattice-parameter changes were exploited in order to reduce the problem of overlapping reflections. The phasing power of two heavy-atom derivatives in a multiple-isomorphous-replacement (MIR) analysis enabled molecular structural information to be obtained up to approximately 5.3 Å resolution. At such a resolution, features of the secondary structure of the lysozyme molecule could be accurately located using programs for this purpose. In addition, the quoted resolution was sufficient to determine the correct hand of the heavy-atom substructure, which led to an electron-density map representing the protein molecule of proper chirality (Fig. 7.1.11) (Basso *et al.*, 2010).

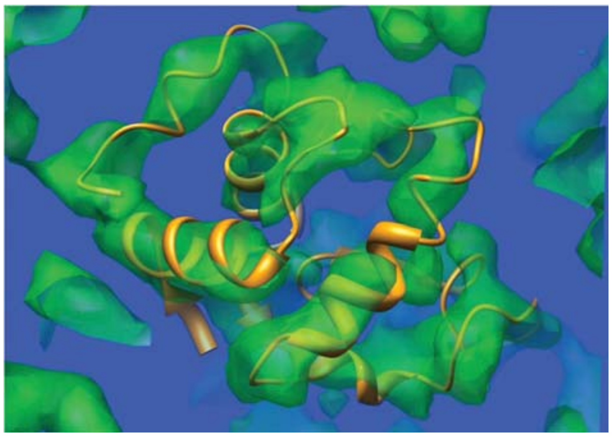

Figure 7.1.11
The electron-density map of HEWL (green) obtained from MIR data after density modification superimposed onto the known molecular structure (orange) obtained from the PDB (PDB code: 6lyt; Young *et al.*, 1993) (Basso *et al.*, 2010).

7.1.7.3. *Emerging powder phasing methods*

With single-crystal samples, the multiple-anomalous-dispersion (MAD) method has revolutionized the process of solving novel protein structures. Unfortunately, in powder experiments, the Friedel pairs hkl and $\bar{h}\bar{k}\bar{l}$ are always exactly overlapped, and so anomalous differences cannot be determined. Nevertheless, dispersive differences due to the variation in f' can be measured. The implications of this systematic overlap problem have been discussed by Prandl (1990, 1994), who reached the conclusion that phases can be determined for centric reflections using a single anomalous scatterer, but for acentric reflections at least two anomalously scattering species are required. Plöhn & Büldt (1986) have also considered the powder phasing problem and discuss the ways in which D_2O/H_2O substitution could be used for labelling with neutron data. The dispersive difference phasing methods were demonstrated by application to $SrSO_4$ by Burger *et al.* (1998), where the centric structure was solved using data near the Sr edge.

Helliwell *et al.* (2005) have collected data at the Ni edge for $Ni(SO_4){\cdot}6H_2O$ and determined optimal choices of wavelengths at the absorption edge. They indicate that the methods may also be applicable to microcrystalline protein samples. Work is in progress in our own laboratory, as well as in others, to exploit the dispersive differences that can be obtained by tuning the wavelength around an X-ray absorption edge for powder data. Helliwell and co-workers recorded high-quality synchrotron X-ray protein powder diffractograms (ID31, ESRF) from K_2PtBr_6 bound to lysozyme at 80 K to protect against X-radiation damage as much as possible and also to fix the K_2PtBr_6 heavy-atom-compound bound state (Helliwell *et al.*, 2010). With multiple-powder-pattern analysis, they then extracted individual reflection intensities and were thus able to show the presence of $PtBr_6^{2-}$ bound in lysozyme in $(F_o - F_c)$ Fourier omit maps at two binding sites. The wavelength-dispersive difference Patterson for the ID31 data at two wavelengths around the Br K edge and also the Pt L_{III} edge showed up binding site 1 in one of the six samples tested. In order to investigate the detailed binding behaviour they conducted single-crystal analyses with time-resolved freeze quenching after lysozyme-single-crystal soak times of 10, 90 and 170 min. Whilst the quick soaking of 10 minutes used in their first experiments at ID31 (ESRF) showed clear binding, there was a steady progression of increasing binding strength with increasing soak time. Thus, these time-resolved analytical-chemistry results show that further heavy-atom signal optimizations, and reproducible behaviour, are possible. The problem identified by Prandl (1990, 1994) for acentric reflections of using more than one anomalous-scatterer type can be approached instead *via* the method of 'solvent flattening'; test calculations in our laboratory with the MAD data of Peterson and co-workers (1996) using only the dispersive differences show that this can be effective in resolving a phase ambiguity (for this brominated oligonucleotide example) when only one anomalous scatterer is present. Recent experiments for extending their approach to the larger isomorphous and wavelength-dispersive signal cases of Ta_6Br_{12} as well as the non-ionic gadolinium chelate Gd(HP-D03A)($C_{17}H_{29}N_4O_7Gd{\cdot}1.3H_2O$) bound to lysozyme for powder experiments have been performed and data analysis is currently in progress. Overall, multiple-heavy-atom cluster compounds such as K_2PtBr_6 and Ta_6Br_{12} offer a way forward to solve *de novo* protein structures by powder diffraction as a complement to microcrystallography (Hedman *et al.*, 1985). Experience does suggest, however, that freezing a bulk lysozyme powder loaded with Ta_6Br_{12} is not as easy as freezing a single crystal soaked in Ta_6Br_{12}.

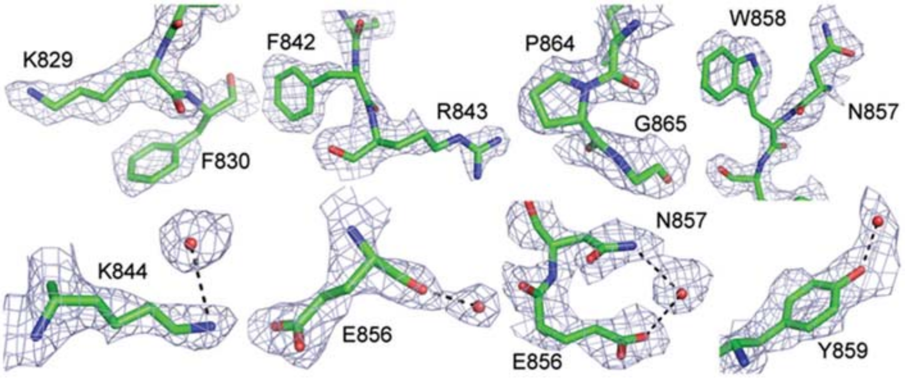

Figure 7.1.13
Selected regions of the final refined structural model of the second SH3 domain of ponsin in stick representation and the corresponding total omit map contoured at 1σ. This figure was generated using *PYMOL* (http://pymol.sourceforge.net/) (Margiolaki, Wright, Wilmanns *et al.*, 2007).

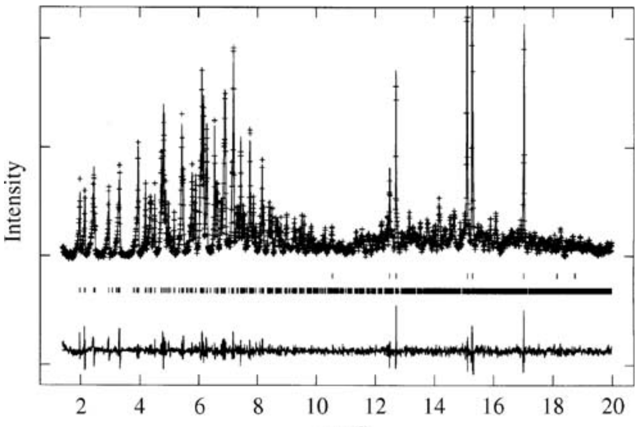

Figure 7.1.12
X-ray powder-diffraction profile from the final Rietveld refinement of whale metmyoglobin. Observed intensities are shown as crosses (+), calculated and difference curves as lines, and reflection positions for $(NH_4)_2SO_4$ and the protein as shown as vertical tick marks. The background intensity found in the refinement has been subtracted from the observed and calculated intensities for clarity (Von Dreele, 1999).

7.1.8. Structure refinement

7.1.8.1. *Stereochemical restraints*

In 1999, the first protein structure refinement using powder data was reported (Von Dreele, 1999) for metmyoglobin. High-angular-resolution synchrotron data from beamline X3B1 (λ = 1.14991 Å) at the National Synchrotron Light Source (NSLS), Brookhaven National Laboratory, USA, were used for the refinement (Fig. 7.1.12). A key characteristic of the powder profile was the observation of very sharp reflections associated with the highly crystalline protein sample. By combining a suite of stereochemical restraints with the measured diffraction profile, a successful refinement of the atomic positions of the 1260-atom protein was achieved (PDB code: 1f6h). In order to carry out this refinement, Von Dreele upgraded the *GSAS* (Larson & Von Dreele, 2004) software package in several ways. A suite of stereochemical restraints, as are normally used in low-resolution refinements with single-crystal data, was implemented with automatic recognition of atom and bond types for the standard amino-acid residues. A novel restraint was introduced to describe the two-dimensional pseudo-potential surface of a Ramachandran plot (Ramachandran *et al.*, 1963). Also, a Babinet's principle solvent correction was used to account for the disordered solvent within the crystal structure. The excellent Rietveld fit obtained was a breakthrough, showing for the first time that a crystal structure refinement could be carried out for a protein molecule from powder data.

Structure refinements can be significantly improved by the use of multiple data sets, provided there are not significant changes in the structure factors between the different data sets. Two independent investigations of HEWL showed that the use of multiple patterns associated with slightly different lattice parameters leads to enhanced extracted intensities and more robust structure refinements (Basso *et al.*, 2005; Von Dreele, 2007) using a modified version of *GSAS* which could account for small lattice strains in different patterns (Larson & Von Dreele, 2004). In our laboratory, we prepared a total of 44 different polycrystalline HEWL precipitates at 277 K and room temperature, and in the pH range between 6.56 and 3.33 (Basso *et al.*, 2005). High-resolution powder-diffraction data were collected at room temperature (λ = 1.249826 Å, ID31, ESRF). The anisotropic effect of pH of crystallization on the lattice dimensions of tetragonal HEWL shifts the peaks significantly and alleviates the peak-overlap problem. In order to try to quantify the improvements coming from the multiple-data-set approach, we selected four patterns across the range of pH for use in a multi-pattern Pawley (1981) refinement. Reflections with a reasonable signal-to-noise ratio could be observed visually in all data sets up to a maximum resolution of about 3.27 Å. We tried to find a way to quantify the resolution limit of these multi-pattern data sets by following the methodology described by Sivia (2000). The least-squares matrix from a multi-pattern Pawley refinement characterizes the data set, and the eigenvalue spectrum of this matrix is related to the effective error estimates on the extracted intensities (or linear combinations of intensities when peaks are overlapped). To provide easier comparison with single-crystal data-processing statistics, we computed the effective completeness for the combined data set as the fraction of 'peaks' having $I = \sigma(I)$ greater than some threshold. This analysis showed the significant improvement of the effective completeness as a result of the use of multiple profiles during intensity extraction. Von Dreele (2007) has proposed a computationally simpler scheme which also attempts to quantify the improvements arising from the use of multiple data sets, and can also be applied to Rietveld refinements. The same four histograms as used for the completeness analysis were employed in a multiple-data-set Rietveld refinement (Rietveld, 1969) in order to extract an average structural model for tetragonal HEWL using *GSAS* (Larson & Von Dreele, 2004). Some differences between diffraction patterns could be accounted for by allowing the solvent-scattering coefficients to differ for each one of the four histograms, following the observation that the largest observed differences in peak intensities were mainly at low angles. A more detailed description of this refinement can be found in Basso *et al.* (2005) and the model is deposited in the PDB with access code 2a6u. We found that this approach resulted in a much smoother and more robust refinement than previously experienced with single-pattern fits and produced a structural model with excellent stereochemistry. Von Dreele has also applied a multi-pattern approach to HEWL but using data sets obtained from an image plate and approaching single-crystal resolution limits ($d_{\min}$ ~ 2 Å). The patterns differ because of changes in salt concentration and radiation-induced lattice strains. Anisotropic changes in the unit cell are taken into account in all of these refinements using a special profile function implemented in *GSAS* (No. 5). Using this function, only one set of unit-cell parameters is refined, and those corresponding to the other patterns are related *via* a strain ($\Delta d/d$) of the reciprocal metric tensor elements. By selecting different combinations of data sets, Von Dreele refined three structural models and was able to add water molecules in each case (PDB codes: 2hs7, 2hs9 and 2hso). Many of these water molecules are conserved between the three models and have also been found in single-crystal structures. The stereochemistries of the resulting multiple-data-set models show significant improvements in comparison to previous single-pattern powder refinements.

In one of our most recent studies of the second SH3 domain of ponsin (Margiolaki, Wright, Wilmanns *et al.*, 2007), we exploited radiation-induced anisotropic lattice strains in a specially modified multi-pattern Pawley refinement, taking into consideration likelihood criteria for partitioning overlapped peaks (Wright *et al.*, 2007). The outcome of this analysis was a set of improved extracted intensities, in excellent agreement with single-crystal intensities later obtained by an independent experiment. The powder data were sufficient for the structure solution of the domain *via* the molecular-replacement method as described in Section 7.1.7.1. Maximum-likelihood refinement improved the phases to a level where we could trace the main-chain alterations,

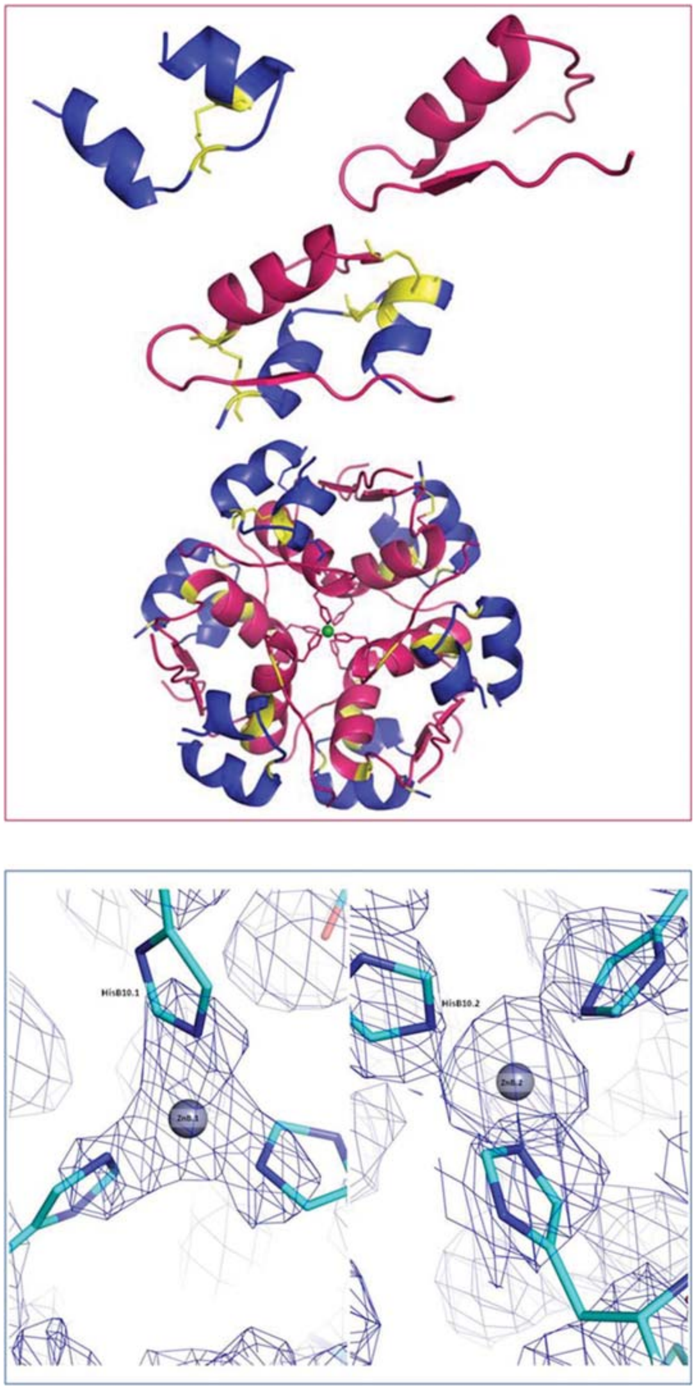

Figure 7.1.14
Upper panel: Powder-diffraction structure of the T6 bovine insulin (BI) hexamer. BI consists of two chains, A (21 amino acids) shown in blue and B (30 amino acids) shown in purple. Chain A contains a disulfide bond between two cysteines. The chains are held together by two disulfide bonds in order to form a monomer. Three monomers form the T6 hexamer shown. The Cα trace is viewed down the crystallographic threefold axis. The zinc ions are shown as red spheres. Each of two independent zinc ions is octahedrally coordinated by three histidine side chains shown in green. Because both zinc ions lie on the threefold axis, only one is visible in the drawing. Lower panel: Selected regions of the total omit map at 1σ clearly indicating the positions and coordination of the two zinc ions present in T6 BI. The map was computed at the initial stages of our analysis employing only the protein atoms (excluding all ligands) from the 2a3g PDB model (Smith *et al.*, 2005) and the extracted intensities from the seven-pattern combined Pawley fit. The map was computed using *SFCHECK*. The residues represented in green stick carbon atoms correspond to the final refined model and the red spheres represent the two independent zinc ions, which are octahedrally coordinated by three HisB10 side chains (Margiolaki *et al.*, 2013).

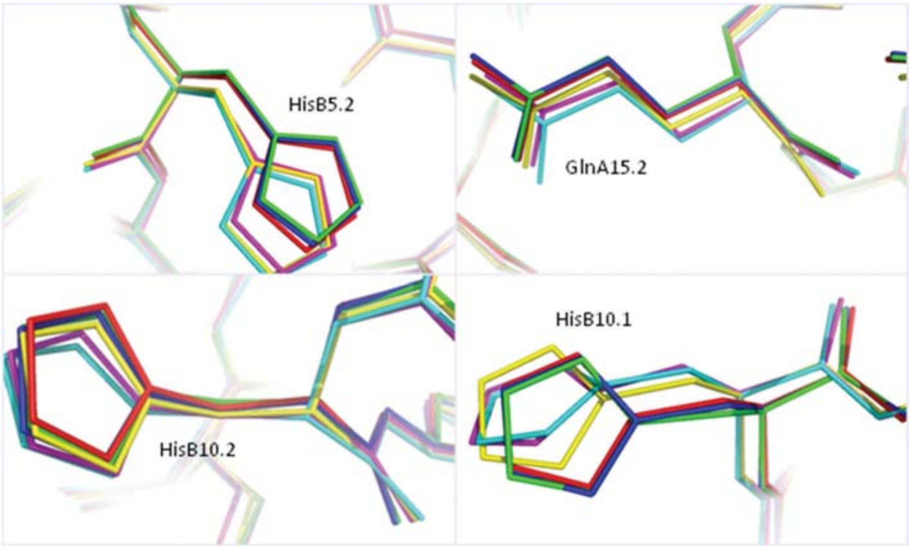

Figure 7.1.15
Evolution of selected amino acids along the protein chains during the Rietveld refinement procedure for T6 BI in *GSAS*. The amino-acid labels denote the residue type, amino-acid number in accordance with the 2a3g PDB model and monomer number (1 or 2). The red, green, blue, yellow, magenta, cyan and orange colours correspond to the refined model at subsequent stages of our analysis (Margiolaki *et al.*, 2013).

build additional residues where needed and eventually place the correct side chains along the sequence; a substantial result from powder-diffraction data. The protein conformation was refined in a multiple-data-set stereochemically restrained Rietveld analysis taking advantage of sample-induced anisotropic lattice strains. We further benefited from an approach combining multiple-data-set Rietveld analysis and periodical omit-map (Bhat, 1988) computation to reduce the bias of the final model, extending the resolution limits to levels comparable to single-crystal measurements, and even detecting several water molecules bound to the protein (Fig. 7.1.13). The benefits of the multi-pattern approach are perhaps most striking from the high quality of the computed omit map shown in Fig. 7.1.13.

7.1.8.2. *Rigid-body representation of amino-acid residues*

An efficient way of describing the structure of a protein has recently been implemented in *GSAS*, where each amino acid is represented by a flexible rigid body (FRB). The origin of each FRB is the location of the Cα atom and the orientation is described *via* a quaternion, thus requiring six adjustable parameters. The side chain of each amino acid has adjustable torsion angles and the orientations of the carbonyls (ψ angles) are also allowed variables for each FRB. All bond lengths and angles within each FRB are fixed at the ideal values. Restraints are then only needed for the interatomic distances and angles about the C—N coupling between amino acids along the polypeptide chain and for the torsion angles. This rigid-body model requires just over one-third of the number of refinable parameters in a full free-atom refinement, thus making it better suited for Rietveld refinement of proteins. This approach has been applied to SXRPD data (ID31, ESRF) of the T6 polymorph of bovine insulin. The number of parameters in the FRB refinement was 700, compared with the 1767 that would be needed for a free-atom refinement. Moreover, the use of idealized amino-acid bond lengths and angles in each FRB lowers the number of restraints from 1980 required for the free-atom refinement to just 400 for the FRB refinement. The refinement was robust, leading to convergence and a refined structural model of excellent stereochemistry in good agreement with the known single-crystal structure (PDB code: 2a3g). The structure is trigonal with three insulin dimers, where each monomer consists of two protein chains forming an hexamer, which is held together by two Zn atoms (Fig. 7.1.14). The correct positions and octahedral coordinations of both Zn atoms were immediately identified from total omit maps (Bhat, 1988) generated in the initial steps of our analysis and added to the structural model. The gradual evolution of selected side chains of individual amino acids during the refinement procedure is illustrated in Fig. 7.1.15 (Margiolaki *et al.*, 2013).

7.1.9. Related developments

Other techniques that seek alternatives to single-crystal structure analysis, and which are therefore interesting with respect to some aspects of this summary of macromolecular powder diffraction, are being developed. Obviously, the characterization of pharmaceutical samples which are absorbed by a patient in bulk form, such as insulin crystalline slurries, can only be characterized by powder diffraction. The alternatives to single-crystal analysis include methods that seek to work with a nanocrystal or even a single molecule, most notably at the new X-ray laser facilities. There are exciting developments with electron diffraction too, notably *via* the new precession-electron-diffraction technique. These developments are briefly summarized below.

The recent exciting results obtained at fourth-generation X-ray sources (X-ray free-electron lasers) demonstrated a method for structure determination where single-crystal X-ray diffraction ‘snapshots’ are collected from a fully hydrated stream of nanocrystals using femtosecond pulses from a hard-X-ray free-electron laser (Chapman *et al.*, 2011; Hunter *et al.*, 2011; Hunter & Fromme, 2011). They proved this concept with nanocrystals of photosystem I, one of the largest membrane-protein complexes. More than 3 000 000 diffraction patterns were collected in this study, and a three-dimensional data set was assembled from individual photosystem I nanocrystals (from 200 nm to 2 µm in size). The problem of radiation damage in crystallography was mitigated by using pulses briefer than the timescale of most damage processes. This certainly offers a new approach to structure determination of macromolecules that do not yield crystals of sufficient size for studies using conventional radiation sources or that are particularly sensitive to radiation damage. In 2012, Aquila and co-workers (2012) reported the first time-resolved femtosecond serial X-ray crystallography results related to light-induced changes of photosystem I–ferredoxin co-crystals observed at time delays of 5 to 10 µs after excitation. This technique opens the door to time-resolved structural studies of reaction dynamics in biological systems. Furthermore, protein crystallization in cells has been observed several times in nature. However, owing to their small size these crystals have not yet been used for X-ray crystallographic analysis. Koopman and co-workers prepared nanometre-sized *in vivo*-grown crystals of *Trypanosoma brucei* enzymes and applied the emerging method of free-electron-laser-based serial femtosecond crystallography to record interpretable diffraction data. This combined approach will open new opportunities in structural systems biology (Koopmann *et al.*, 2012).

On the other hand, the electron diffraction (ED) technique utilizes the electron beam generated by a transmission electron microscope (TEM) and thus measurements can be performed routinely. Electron diffraction and X-ray powder diffraction are remarkably complementary techniques. Electrons interact much more strongly with matter than X-rays, so a single-crystal electron-diffraction pattern can be obtained from a very tiny crystallite. The disadvantages that hindered the development of electron crystallography until recently were the strongly dynamical diffraction of electrons and the resulting non-trivial relation of the measured intensities to the structure-factor amplitudes. The precession-electron-diffraction (PED) technique, first described by Vincent & Midgley (1994), has already been employed for the structure solution of zeolites (McCusker & Baerlocher, 2013; Xie *et al.*, 2008) and other families of compounds including small pharmaceuticals (Dorset, 1995; Voigt-Martin *et al.*, 1997; Kolb *et al.*, 2007; Eddleston *et al.*, 2013). Diffraction experiments can be conducted on crystals with a diameter of the order of 50 nm. An individual particle of a powder sample can therefore be used as a single crystal for diffraction. PED data may be exploited in two different ways: (1) to identify weak reflections and (2) to estimate the phases of the reflections in the projection. The former is used to improve the partitioning of the reflection intensities within an overlap group and the latter to provide some starting phases for structure determination. Furthermore, the problems often stemming from a possible mixture of polymorphs in the powder sample can be overcome *via* ED methods by selecting individual crystals with the desired structure.

7.1.10. Concluding remarks

This chapter summarizes the advances of the macromolecular powder-diffraction method achieved during the last decade. Although developments of both experimental and computational aspects are still in progress, results obtained to date demonstrate that this is a technique ready to tackle genuine biological problems. The choice of the instrumental configuration is critical for obtaining the highest possible information from the collected profiles. The use of a lower-angular-resolution instrument allows construction of phase diagrams and checking for ligand or heavy-atom binding to be carried out rapidly using small quantities of powder sample. On the other hand, the analyser-crystal beamlines offer unparalleled instrumental resolution, which is very attractive in reducing the peak overlap. The unit-cell parameters are perturbed to alter the pattern of peak overlaps in the different data sets and reduce the overlap problem. Ultimately, in cases where this approach was used, it led to enhanced results in comparison to a single-pattern analysis.

High-throughput crystal screening requires a multivariate data-analysis strategy for fingerprinting in order to compare similarities and differences between the various patterns corresponding to different samples. A successful method used for the characterization of insulin microcrystals (Norrman *et al.*, 2006; Valmas *et al.*, 2015; Fili *et al.*, 2015) is principal component analysis (PCA) (Jolliffe, 1986; Wold *et al.*, 1987; Barr *et al.*, 2004). Several software packages are already available that have incorporated (among other methods) PCA for easy visualization of the total data variation of multiple powder-diffraction patterns. The aim of this method is to arrange a series of diffraction patterns into clusters based on their mutual similarities, allowing dominant patterns and major trends to be rapidly identified.

To date, data interpretation is performed *via* the combined use of software packages designed for powder diffraction as well as single-crystal diffraction data. Consequently, data analysis is often complex and time consuming, It is essential to improve the current algorithms in order to enhance and automate data analysis. For example, existing molecular-replacement (*MOLREP*/ *PHASER*) (Vagin & Teplyakov, 1997; McCoy *et al.*, 2007) and refinement (*REFMAC*) software (Murshudov *et al.*, 2011), which was initially designed for single-crystal data and is available from the *CCP4* suite (Collaborative Computational Project, Number 4, 1994), needs to be adapted for use with powder data by taking peak overlap into consideration. Algorithms for extracting reliable structural information from medium-resolution data (4.5–8 Å) are, as yet, still relatively scarce (Karmali *et al.*, 2009; Brunger *et al.*, 2009). However, this is expected to change as the gap between electron micoscopy and high-resolution X-ray diffraction is bridged.

According to statistical information provided in the PDB, 94 730 protein structures have been determined by means of X-ray diffraction to date. Some of these structures have been used for the development of drugs already available in the market for the treatment of diseases such as diabetes or HIV. Crystallization may be employed in order to formulate a protein–drug complex (Yang *et al.*, 2003; Basu *et al.*, 2004). Protein microcrystals have better stability and higher concentration than proteins in solution for storage and have a lower manufacturing cost compared with lyophilization. The polymorphism of the crystals has to be fully characterized in order to formulate a drug in solid form; this is mandatory for the drug's approval by health authorities. Powder diffraction is in this case the most suitable tool for the characterization of different polymorphs, as it provides information on numerous microcrystalline suspensions. Further advantages that are gained from the use of microcrystalline samples and powder-diffraction measurements include verification of the homogeneity and phase purity of the protein precipitates; the extraction of accurate lattice parameters, allowing direct observation of slight structure modifications; and exploitation of radiation- and sample-induced effects.

Finally, it is anticipated that the combination of powder diffraction with other experimental techniques, including X-ray microcrystallography of biological macromolecules (Hedman *et al.*, 1985; Evans *et al.*, 2011), serial X-ray crystallography at free-electron lasers (Hunter *et al.*, 2011) and electron-diffraction methods, could considerably enhance the structural characterization of materials employing nanocrystals.

The powder X-ray diffraction method applied to biological macromolecules is coming of age. It certainly has emerged out of the young-child phase to the teenager phase; various refinements of the method are needed, but to see this 'young adult' technique successfully emerging in its applications even thus far is delightful.

I am grateful to Professor A. N. Fitch, Dr J. P. Wright and Dr R. B. Von Dreele for their continuous input, advice and support during this project. In particular, the results and software packages produced by R. B. Von Dreele over the last decade led to the renaissance of the application of powder methods to proteins, an old idea which had not been exploited systematically in the past. I would like to thank six undergraduate students from the University of Bath who have worked with us for one year each: S. Basso, L. Knight, S. Dagogo, M. Jenner, I. Collings and L. Saunders, as well as our postdoctoral researcher, Y. Watier. I am also grateful to Professor J. R. Helliwell for the critical reading of this chapter and his advice for including practical information for non-experts in this scientific field. I am grateful to our collaborators Drs G. C. Fox, M. Norrman, G. Schluckebier, M. El Hajji, D. Beckers, T. Degen, F. Bonnete, M. Giffard, N. Papageorgiou, B. Canard, B. Coutard, M. Wilmanns, N. Pinotsis and K. Miura. I would like to thank Dr M. Schiltz and his group and especially Celine Besnard, for their help and collaboration. I would also like to thank my postgraduate/undergraduate group members at the University of Patras: Anastasia Giannopoulou, Fotini Karavassili, Eleni Kotsiliti, Marina Kalatha, Alexandros Valmas, Stavroula Fili, Konstantina Magiouf and Danae Lahana. I am grateful to the UNESCO and L'Oreal foundations for the International Fellowship for Women in Science (2010–2012). Part of this research has been co-financed by the European Union (European Regional Development Fund – ERDF) and Greek national funds through the Operational Program 'Regional Operational Programme' of the National Strategic Reference Framework (NSRF) – Research Funding Program: Support for research, technology and innovation actions in Region of Western Greece (Karatheodoris foundation). Since 2012, the EU FP7 REGPOT CT-2011- 285950 – 'SEE-DRUG' project and the companies NanoMEGAS, Novo Nordisk and PANalytical support the continuation of our work on macromolecular powder diffraction. Part of the research presented in this chapter has been co-financed by the following grants: (*a*) The International Atomic Energy Agency (CRP code: F12024), (*b*) The European Union (European Social Fund) and the Greek State under the 'ARISTEIA II' Action of the 'OPERATIONAL PROGRAMME EDUCATION AND LIFELONG LEARNING' and (*c*) The COST action (CM1306). Finally, we thank the ESRF, DESY and the SLS synchrotrons for provision of beam time. This chapter is dedicated to the memory of Dr Richard Kahn, an exceptional crystallographer, teacher and friend.

7.2. Forensic applications of X-ray powder diffraction

D. F. Rendle

7.2.1. Introduction

7.2.1.1. *Background information*

X-ray powder diffraction (XRPD) as a method of chemical analysis was first described in a paper by Hull (1919), in which he stated the following:

> Every crystalline material gives a diffraction pattern; the same substance always gives the same pattern; in a mixture of substances each substance will produce its own pattern independently of the others, so that the diffraction pattern obtained will be the superimposed sum of the patterns that will be obtained by exposing each of the components separately for the same length of time. This law applies quantitatively to the intensities of the lines (provided the absorption is negligible for each of the components) as well as to their positions, so that the method is capable of development as a quantitative analysis.

Such diffraction patterns are a ‘fingerprint’ of the particular crystalline substance. However, as with human fingerprints, there must be a known standard with which to compare the unknown before the pattern can be of value (Marvin & Garbarino, 1953). These beautifully concise statements tell us all we need to know about the method, and today, almost 100 years after Hull’s publication, forensic analysts use XRPD with varying degrees of sophistication, for both qualitative and quantitative analysis, based upon those principles first stated by Hull.

Forensic science is the science that is used in a court of law, whether it be a criminal or civil court (Walls, 1974). Hans Gross (1847–1915), professor of criminology at the University of Prague, is generally recognized as one of its pioneers, and his classic publication *Handbuch fur Untersuchungsrichter* first appeared in 1893. The English translation, entitled *Criminal Investigation* (Gross, 1962), first appeared in 1906, and in it was stressed the help that science could give to the detective. Gross was a lawyer rather than a scientist, however, and did not contribute to the development of scientific methods. The greatest contributions in that field were probably those made or inspired by Edmond Locard (1877–1961) of the University of Lyon. His guiding principle, that ‘every contact leaves a trace’, known as Locard’s Exchange Principle, still figures prominently in lectures delivered on the subject of criminalistics.

So-called ‘contact traces’ appear in the traditional areas of forensic science, where the identification and comparison of trace quantities of material can help in the conviction or exoneration of a person suspected of involvement in a crime. Examples of contact trace materials include paint flakes, glass fragments, hair and fibres (natural and synthetic), slivers of metal, soils, building materials, plastics and polymers, stains of any description, cosmetics, explosives and gunshot residues, corrosion products, and loose powdered materials including drugs of abuse. The most important of comparisons is that between so-called ‘control’ and ‘suspect’ specimens. For example, in the case of a burglary in which the burglar has forced entry through a window, any paint flakes and glass fragments found on his outer clothing would constitute ‘suspect’ specimens and paint and glass specimens taken from the windowsill and pane by a crime scene investigator would be the ‘control specimens’.

Prior to the discovery of individual-specific ‘fingerprints’ of human DNA and subsequent forensic application of DNA fingerprints (Gill *et al.*, 1985), much time and effort was expended in the labour-intensive detection and analysis of such contact traces in attempts to prove, or disprove, links between a person suspected of involvement in a crime and the victim and/or crime scene. The advent of DNA profiling, however, meant that law-enforcement agencies now had at their disposal a means that would provide them with reliable, highly individual-specific evidence. Understandably, many of these agencies then began to rely heavily upon DNA evidence at the expense of the less individual-specific evidence generated by what were once known as classical contact trace materials. However, in the absence of material leading to the recovery of DNA, and of human finger marks, which are also individual-specific, the analysis and comparison of such trace materials once again becomes important, and one of the most useful and versatile methods for their analysis is X-ray powder diffraction. Some general articles describing the analysis of these materials and others by XRPD are available: Thatcher & Briner (1986), Fischer & Hellmiss (1989), Rendle (2000), Liberman (2000), Kügler (2003), Rendle (2003*a*,*b*), Heijnen *et al.* (2005), Kügler (2005), Kotrlý & Bezdička (2006), Abraham *et al.* (2007), Kotrlý (2007), Švarcová *et al.*, (2010) and Kotrlý (2011).

7.2.1.2. *Preservation of evidence*

The need for non-destructive methods of analysis in order to preserve evidence can be of great importance, although this requirement may vary from country to country or from state to state depending upon the prevailing criminal justice system. Even if preservation of the specimen for legal reasons is not required, non-destructive analysis means that the specimen may then be subjected to further complementary analyses. Most courts understand and accept that chemical analysis may occasionally result in destruction of a specimen, but in certain circumstances may insist on seeing the specimen that was analysed, and perhaps having that same specimen re-analysed by another scientist. In view of this, it is wise to use, where possible, a non-destructive analytical method as a matter of course, and XRPD meets this requirement admirably.

7.2.1.3. *Versatility*

XRPD probably ranks as one of the most versatile methods of instrumental analysis because it can be used to analyse any solid substance, crystalline or partially crystalline, whether it be organic, inorganic, metallic or a mixture thereof. Its main drawback is its lack of sensitivity; it is not a true trace technique. Although it is capable of analysing very small specimens, if one of the chemical components within the specimen is present at a low concentration, it may well go undetected. However, as long as the limitations of the method are known and understood, and it is used intelligently, XRPD will yield qualitative and quantitative results unrivalled by other techniques.

7.2.1.3.1. *Drugs and toxicology*

Review articles (Clarke, 1962; Schmidt, 1962) indicate that some of the earliest published uses of XRPD methods in forensic science were in the 1950s (Huang & Jerslev, 1951; Huang, 1953), and concerned the analysis of drugs, specifically barbiturates. Unpublished work from the Toxicology Section of the Metropolitan Police Forensic Science Laboratory (London, UK) in the 1950s revealed that small-diameter Debye–Scherrer powder cameras were used to identify barbiturates (Jackson, 1977). The identification of barbiturates isolated from biological material was a difficult task for forensic chemists, and when more than one barbiturate was present it was almost impossible to isolate them in a pure enough state for melting points to be determined accurately. The problem was further complicated by the polymorphism (the ability of the same substance to crystallize in different forms) shown by many of these compounds, and by their tendency to form mixed crystals if two or more of them are present (Mesley *et al.*, 1968). Pinker (1952) indicated that XRPD had been used for barbiturate and general drug analysis some years earlier still, although no specific dates were given. A diffractometer was used in which the specimens covered thinly an area of about 6 mm^2 on a lead slide. The diffraction patterns were recorded on a moving strip of chart paper, and 16 patterns of drugs were shown. Further work on drug analysis (Marvin & Garbarino, 1953) using diffractometry was published, with reference to the importance of uniform specimen preparation, and a list of the perceived advantages and disadvantages of XRPD as an analytical method.

The analysis of opiates by XRPD methods was discussed even earlier than in those instances just described (Gross & Oberst, 1947; Oberst, 1938, 1943; Hubach & Jones, 1950), although in these cases the applications were not strictly forensic. Similarly, XRPD was used (Parsons, 1952) to identify cystine as the only constituent of a radiopaque renal calculus, and by Parsons & Beher (1955) to amass a collection of powder data on steroids, a project that was further extended (Parsons *et al.*, 1958). Barnes (1954) described in detail the powder method with particular emphasis on its use in the analysis of narcotics, and, in a co-authored paper, provided the first real collection of tabulated numerical XRD powder patterns of narcotics (Barnes & Sheppard, 1954). Cocaine and its substitutes were analysed by XRPD (Sullivan & O'Brien, 1970). Powder data for 17 local anaesthetics (Owen *et al.*, 1972), for some drugs, excipients and adulterants (Folen, 1975), and for piperidyl benzilates and related glycolates (Barrick *et al.*, 1977) have since been added to the Powder Diffraction File (ICDD, 2014). More recently Thangadurai *et al.* (2005) have emphasized the value of powder diffraction in the forensic analysis of a number of β-lactam, tetracycline and macrolide antibiotics.

In addition to identifying the precise chemical form of drugs (salt, base, acid), XRPD also provides information about the excipients (materials mixed with the drugs, both organic and inorganic) in drug seizures. In general these substances tend to be carbohydrates such as glucose, mannitol and occasionally sucrose, although a number of other more unusual compounds are sometimes encountered (Rendle, 2003*b*, 2004; Rendle & Connett, 1988; Ferguson *et al.*, 1991). The method has other important uses in forensic drug analyses, too, namely distinguishing between (*a*) polymorphic forms of drugs and excipients, (*b*) optically active and racemic forms of drugs, and (*c*) different hydrated forms of drugs and excipients. Barbiturates are prime examples of drugs with multiple polymorphic forms (Mesley *et al.*, 1968), whilst aspirin, ibuprofen and paracetamol (acetaminophen) have at least one polymorph each. Mannitol may appear as an excipient in drug/excipient mixtures in any one of three common polymorphic forms (α-, β- or δ-D-mannitol). Methylenedioxymethylamphetamine hydrochloride, commonly known as MDMA·HCl or ecstasy, is known to exist in a number of hydrated crystalline forms (Shulgin, 1986). The monohydrate of ecstasy has been encountered in drug seizures and its XRPD pattern has been identified and recorded (Rendle & Glazier, 2012). Gamma-hydroxybutyrate (GHB) is a sleep-inducing drug and has been used in cases of drug-facilitated sexual assault ('date rape'). Ferris & Went (2012) used XRPD to discriminate between four different salts of the drug. In a study on ecstasy and amphetamine seizures in Spain during 1995–2002, Pastor *et al.* (2003) used XRPD in conjunction with gas chromatography–mass spectrometry (GC-MS), high-performance liquid chromatography (HPLC) and Fourier transform infrared spectroscopy (FTIR) to identify the active drug components, excipients and precursors. Identification of *all* components in drug seizures is important from an intelligence aspect because chemical similarities between several seizures may indicate a common source of the drugs, *i.e.* one, as opposed to more than one, drug dealer (Rendle *et al.*, 2011). Synchrotron radiation was used to generate XRPD patterns for the comparison of a number of methamphetamine samples from different sources (Terada, 2005).

7.2.1.3.2. *Paint and pigments*

Forensic paint analysis 50 years ago usually meant identifying inorganic pigments, fillers and extenders (Heilman, 1960; Scott, 1969), but the growth of the organic pigment industry in the following years and the resultant increase in use of organic pigments in paint manufacture presented a new challenge for the analyst. Organic pigments are generally poorer scatterers of X-rays than their inorganic counterparts, yielding fewer diffraction data, and some organic pigments, because of their intense colouration, tend to be present in lower concentration than inorganic pigments in paints. In addition, the optimum particle diameter for pigments in paints is approximately 0.2–0.4 µm (200–400 nm) (Bentley & Turner, 1998), which may result in diffuse or broadened diffraction maxima. A general paper on pigment analysis (Kamarchik, 1980) appeared, and Curry *et al.* (1982) produced a list of the powder patterns of 71 organic pigments. These diffraction data enabled identification of pigments in paints, bearing in mind the comments above, and provided that their concentration in the paint was sufficiently high for detection by XRPD.

Decorative, automobile, tool and security paints contain resins, pigments and extenders. The pigments and extenders are usually crystalline, while the resins are not; thus paint may be described as a partially crystalline substance. Nonetheless, tiny paint flakes 0.1 mm^2 in area and weighing a few micrograms can yield diffraction patterns enabling comparison of control and suspect flakes. Under favourable circumstances the pigments and extenders may be identified as well, providing the forensic scientist with some means of assessing the evidential value of a positive match, should one occur. For example, white gloss paints rarely contain any other pigment than rutile, whereas red, blue, green or yellow paints may contain a variety of different pigments. Thus a match between diffraction patterns of white control and suspect paint flakes means far less than one between those of coloured paint flakes containing combinations of 'unusual' pigments and extenders. Polymorphism is not restricted to drugs and/or excipients, because titanium dioxide (the white paint pigment known as rutile) exists in two other ambient temperature forms – anatase and brookite, whilst calcium carbonate (another constituent of some paints) also has three main polymorphs: calcite, aragonite and vaterite.

7.2.1.3.3. *Pathology*

Establishment of the post-mortem interval (PMI) is a complex problem because of the number of intrinsic factors that may alter the normal course of post-mortem change, such as the age, sex, constitution, and previous physiological and pathological states of the subject, and external factors. XRPD parameters related to the degree of crystallinity of the mineral component (hydroxyapatite) in conjunction with biochemical analyses of long bones is suggested as a useful alternative for dating osseous remains (Prieto-Castelló *et al.*, 2007).

Much effort has been made to extract useful information from burned bone. Piga *et al.* (2009) suggested a method of determining the temperature and duration of burning of human remains in a forensic context, by application of XRPD to samples of human bone and teeth. Growth of hydroxyapatite crystallites was found to be a direct and predictable function of the applied temperature (473–1273 K) and duration of burning (0–60 min).

Crystallinity (the degree of long-range order) in bone mineral is increased markedly, at the expense of smaller, more disordered crystals of hydroxyapatite, as a result of diagenesis (the physical and chemical changes that occur in bone after burial) or heating (Rogers, Beckett *et al.*, 2010). This property is direction-dependent, however, and when determined by spectroscopic methods results in an average, which can be misleading. XRPD is capable of resolving direction-dependent characteristics, and demonstrates that recrystallization processes associated with heating and diagenesis produce hydroxyapatite crystallites with significantly different physical microstructures. This enables a distinction to be made between, for example, archaeological and contemporary bone specimens.

In a study of inter-species variation in bone mineral, Beckett *et al.* (2011) established significant differences between heated and unheated samples of human bone and bone from 11 other animal species using XRPD. The inter-species variation was measured in terms of the lattice parameters of calcium hydroxyapatite (bioapatite), its crystallinity and its thermal decomposition products upon heating to 1673 K. The characterization of bioapatite in this way has the potential to enable species identification, particularly in distinguishing human from non-human bone in cases of fragmented, burned and pulverized bone.

The ability to distinguish between cremated human remains (cremains) and other powdered materials of similar appearance can be of great importance (Bergslien *et al.*, 2008). In one instance, instead of cremating the bodies of deceased persons, the organization responsible dumped the bodies and provided the relatives with urns containing cement dust, silica and rock of any description.

A study of the composition of gallstones in patients in the age group 20–74 years (Nagpal *et al.*, 1982) revealed anhydrous cholesterol in 62% of calculi and the monohydrate in 46%. Calcium carbonate, identified as calcite and aragonite, was present in 23 and 8% of the calculi, respectively, and apatite (a general name for a series of calcium phosphates) was found in 38% of the calculi. Cholesterol crystals were also found, and identified by XRPD, in fluid from an intracranial cyst (Parsons & Bartone, 1961).

7.2.1.3.4. *Metals and alloys*

In most forensic science laboratories, metallic specimens would usually be analysed by X-ray fluorescence (XRF) or in the scanning electron microscope using energy-dispersive X-ray spectroscopy (SEM-EDS). These are elemental methods of analysis, however, and as such are incapable of distinguishing between the various crystalline phases that may occur in a metal or alloy. A number of counterfeit 500 yen coins (Hida *et al.*, 2001) were examined by a combination of XRPD and XRF with multivariate analysis. The presence of additional Bragg peaks in the powder patterns of nickel-plated coins and the shift in peak positions in patterns of the pressed coins, when compared to those of the genuine coins, enabled them to be classified as nickel-plated counterfeit, pressed counterfeit and genuine. An earlier XRPD study on brasses (Rendle, 1981) showed that useful discrimination was achievable between brass specimens containing α, β and $\alpha+\beta$ phases occurring as contact traces, and that the copper/zinc ratio within a single-phase α-brass could be estimated, in relative terms, with ease to ±1%.

7.2.1.3.5. *Soils and minerals*

Soil has long been regarded as potentially one of the most useful evidence types, but also as one whose provenance and significance has been one of the most difficult to gauge (Rawlins *et al.*, 2006). The soles of our footwear bear traces of what we have been standing in or on, which may in turn indicate where we have been. Similarly, vehicle tyres may carry traces of soil in addition to leaving behind their own characteristic tread marks in that soil. Not surprisingly, XRPD has been used widely for the analysis of soil traces because of the varying type and amounts of mineral content (Bebris, 2003; Ruffell & Wiltshire, 2004; Fitzpatrick & Raven, 2005; Melo *et al.*, 2008; Fitzpatrick *et al.*, 2009; Keaney *et al.*, 2009; Dawson & Hillier, 2010).

Adipocere is a post-mortem product which forms from body fat in the later stages of decomposition and its formation has the ability to slow or inhibit decomposition, so an understanding of the mechanism of its formation in grave soils is of interest to forensic scientists. Factors influencing adipocere formation include the type of grave soil in which the burial has taken place, and experiments with pig flesh buried in various types of soil were undertaken. Analysis of the soil types by XRPD (Forbes *et al.*, 2005) showed that certain types, including sand and silty sand, were able to accelerate adipocere formation when kept moist and in a temperate environment. Similar results were obtained in a more recent study (Durães *et al.*, 2010).

XRPD methods were used for soil and sediment analysis (Brown, 2006) following the exhumation of mass graves in NE Bosnia associated with the massacre of civilians in and around Srebrenica in July 1995. Bodies had been exhumed and transported from the original mass graves to a number of unknown secondary grave sites. An attempt was made to link the primary and secondary sites through soil and other analyses. On the basis of clast lithology, mineralogy, pollen and spore content, all secondary sites could be associated with matching primary sites.

A roadway embankment was constructed in 1995 with 60% fluidised bed combustion ash, 35% stoker ash and 5% class-F fly ash in West Lafayette, Indiana. Heaving of the embankment was observed during and after construction, and the pavement exhibited severe damage at several locations. Forensic XRPD and SEM studies (Yoon *et al.*, 2007) were used to compare the mineralogical phase composition of fresh samples and samples collected from the heaved embankment. Results indicated that the formation of ettringite [$Ca_6Al_2(SO_4)_3(OH)_{12}{\cdot}26H_2O$] led to the swelling of the embankment, which caused cracking of the pavement.

7.2.1.3.6. *Gunshot residues and explosives*

The most commonly used method for detecting and identifying gunshot residue in specimens obtained from skin is SEM-EDS, but this will not permit unequivocal identification of the compounds in such specimens. For example, whilst confirming the presence of lead, it cannot show whether it occurs in the metallic form, as lead oxide, or as lead sulfide – although it must be said that measurement of a Kikuchi pattern could make the identification unambiguous. Primer residues, gunshot residues from the barrel and gunshot residues emitted from the breech of a gun were analysed by XRPD and SEM-EDS (Tassa *et al.*, 1982). The residues were embedded in a thin film of petroleum jelly on a glass slide and analysed by diffractometry. Metallic lead was found to be the main constituent of all the residues tested. In the primer residues were found antimony, calcium silicide, lead sulfide, barium nitrate, barium aluminate and barium calcium silicate, all identified by XRPD. The residues from the barrel and breech were similar to each other, consisting mainly of lead with metallic copper. In some early work, Soldate & Noyes (1947) analysed explosives' constituents with XRPD, and Canfield & De Forest (1977) described a method for analysing and identifying a single crystal of explosive as small as 30 µm in diameter in an explosives residue, by means of a Gandolfi camera.

Beveridge *et al.* (1975) described a systematic procedure for the analysis of explosive residues, after detonating devices containing high and low explosives. The most useful techniques were reckoned to be microscopy, thin-layer chromatography (TLC), XRPD and infrared spectroscopy. Similar work is described in a more recent publication (Beveridge, 2010). The analysis of explosives by XRPD was also described in two papers (Abel & Kemmey, 1975; Higgs *et al.*, 1978). In the latter, although XRPD was used initially to analyse a substance thought to be a residue of explosives, it proved to be a corrosion product, thus removing the suspicion of explosives as having caused an airline disaster.

7.2.1.3.7. *Paper*

Forensic paper examination and analysis is usually associated with ransom notes, threatening letters, anonymous hate mail and wrappings from drug seizures (Heijnen *et al.*, 2005). The examination will more than likely be a comparison of paper from, for example, the ransom note with that found in a suspect's dwelling. XRPD or elemental analysis may be called for, but only after an initial examination by botanical or fibres experts. If the paper were white, for example, such an examination might include thickness and density measurement, observation of mesh marks and watermarks (if present), and maceration of a small sample in order to identify the type and number of each fibre present (Roe, 2012). If the paper were coloured, the dye(s) would be extracted and analysed by TLC. XRPD is used to identify the fillers present in the paper and it can also yield useful information about the crystallinity of the cellulose (Foner & Adan, 1983). A paper's mineral content depends upon its use and appearance. Newsprint and cheap copying paper usually have either no filler (cellulose only) or a clay mineral such as kaolinite, whereas other more expensive papers, of the type used in glossy magazines, have rutile or anatase as fillers. Causin *et al.* (2010) successfully discriminated between 19 different brands of general office paper ($80\ \mathrm{g\ m}^{-2}$) using a combination of XRPD and infrared spectroscopy.

7.2.1.3.8. *Plastics and polymers*

Plastics and polymers (Heilman, 1960; Turley, 1965), perhaps because of their appearance, are usually thought of as being noncrystalline, and in some cases this is true. However, the majority of the more common polymers and plastics are at least partially crystalline, and therefore lend themselves to analysis by XRPD. Plastics such as polyethylene and polypropylene, which find uses in a wide range of domestic and industrial goods, may have pigments added to them for colouration, and often exhibit a range of crystallinity. XRPD can be used to identify the pigments and the polymer, and provide an estimate of the percentage crystallinity. Causin *et al.* (2007) applied the method to the analysis of plastic bags used for packaging drugs. The polymer chains in the polyethylene bags were highly oriented, due to the manufacturing process, so two XRPD measurements were made, one parallel and one perpendicular to the long dimension of the bags. The relative intensities of the 110 and 200 peaks, together with the estimated degree of crystallinity, enabled discrimination between 33 white, matte, plastic bags.

7.2.1.3.9. *Miscellaneous*

Textile fibres are an example of material not usually analysed by XRPD, as other more appropriate techniques are available (Robertson & Grieve, 1999), but analyses have been undertaken on both single fibres (Lynch & Kerrigan, 1981) and pieces of cloth approximately 45 mm in diameter (Abraham *et al.*, 2007).

Cosmetics may occur as contact traces in cases of sexual assault, and the scientist may be asked to compare smears of face powder, eyeliner or lipstick on clothing belonging to the alleged assailant with control specimens owned by the victim. Ward (2000) describes an X-ray spectral database in which the energy-dispersive spectra of a wide range of materials (including cosmetics) are stored for such comparison cases. Abraham *et al.* (2007) demonstrated the use of XRPD in comparing control lipstick smears on glass slides with smears on clothing.

XRPD was used in conjunction with stable isotope profiling (SIP) and microscopy to analyse wooden safety matches (Farmer *et al.*, 2007) when an individual was suspected of attempting to burn materials potentially relating to a murder case. SIP and microscopy were used on the stems of the matches and XRPD to analyse the match heads. SIP showed the scene matches and seized matches to be different, which was confirmed by XRPD and microscopy.

A blue encrustation (Mann *et al.*, 1998) was found on the remains of three US servicemen listed as missing in action and repatriated from Vietnam after 28 years. The identification of the blue material was determined by XRPD and SEM-EDS and was found to be the mineral vivianite [$Fe_3(PO_4)_2{\cdot}8H_2O$]. The presence of this mineral provides information leading to a more complete understanding of taphonomic processes (those processes involved with fossilization).

Kasımiye Medresse is an important educational centre in the province of Mardin in south-eastern Turkey. There is a stain (Tuğ *et al.*, 2005) on the wall of Kasımiye Medresse, considered to be Sultan Kasım's blood. The stained and unstained parts of the wall were examined by XRPD. The unstained wall consisted solely of calcite, and the 'bloodstain' consisted of whewellite ($CaC_2O_4{\cdot}H_2O$) and weddellite ($CaC_2O_4{\cdot}2H_2O$) in addition to calcite. The stain appeared to be a dye made of herbal roots, with henna-containing whewellite mineral as a likely candidate for the 'bloodstain'.

Kela is a commercial rodenticide bait commonly used in Israel. It is made of wheat grains, which, according to its label, contain chlorophacinone. This product was involved in the death case (Azoury & Levin, 1998) of a man in which the victim's female companion was accused of assisting in his suicide and was subsequently convicted. Analysis of the wheat grains revealed zinc phosphide, the use of which is restricted to authorized exterminators only, instead of chlorophacinone. Zinc phosphide was identified using microscopic examination, SEM-EDS and XRPD.

When a firearm used to commit a crime has been disposed of in a body of water, determining the time since immersion may be of importance to the investigation. Adherent corrosion products on the slides of four different types of handguns were identified by SEM/EDS and XRPD (Wogan *et al.*, 2013) after the components had been immersed in (*a*) deionized water and (*b*) saline solution (separate experiments) for 180 d. However, utilizing a general approach in which surface area coverage of corrosion products is the sole consideration is not sufficient to determine the time since immersion. The results indicated possible corrosion mechanisms driving the process in high- and low-chloride environments, and showed the necessity of including the original firearm metal composition, rust composition and ion concentration in any models that attempt to elucidate the time since immersion of handguns.

7.2.1.4. *Variable specimen size*

Forensic specimens can range from the classical minute (microgramme) contact traces such as paint flakes, to large (kilogramme) quantities of illegal or restricted drugs, so the X-ray instrumentation must be capable of accommodating a range of specimen sizes, weights or volumes as well as specimen types.

7.2.1.5. *Contamination*

By their very nature, or the circumstances under which they are found, some forensic samples will be contaminated, and it is important for the analyst to recognize contamination as such, and not to mistake it for part of the true chemical makeup of the specimen. This will usually be evident upon microscopic examination of the original sample. Any contamination should be noted, however, as its presence may have particular significance when comparing control and suspect specimens.

7.2.1.6. *Identification versus comparison*

Forensic analyses can be categorized as follows: those simply requiring identification, and those requiring comparison of two or more samples in order to establish or preclude a common origin. For identification, a source of reference diffraction patterns is required. This may consist of a selection of 'standard' X-ray powder patterns produced in-house from pure, certified materials, or those contained in the comprehensive Powder Diffraction File, generated and marketed by the International Centre for Diffraction Data (ICDD, 2014). This file contains, at present, upwards of 700 000 powder diffraction patterns of single-phase organic, inorganic and metallic substances. Comparison cases need not *necessarily* require identifications, but it would be most unusual to make comparisons without identifications. Quantitative analysis (Madsen & Scarlett, 2008) may be attempted by either single-peak methods or by whole-pattern fitting, including the Rietveld method (Young, 1993).

7.2.1.7. *Complementary techniques*

In any analytical laboratory, the techniques available will be those dictated by the industry itself, such as pharmaceuticals, metallurgical, electronics, building construction, foodstuffs, polymers and plastics, geosurvey *etc*. A typical forensic science laboratory will not have the resources to attempt the kind of specialist analyses undertaken routinely by each of these major industries; nonetheless, its staff will be expected to cope with analyses of *all* kinds of material. Techniques available in a forensic science laboratory are likely to be dependent upon the type of evidence most frequently submitted for examination, and also upon the resident expertise. It is not surprising, therefore, that many forensic science laboratories will attempt to use the same instrumental technique for a variety of substances, even though it might not be the first choice for a given material, as long as it generates relevant analytical information.

Methods of drug analysis are traditionally solution based, even though a large proportion of samples submitted for analysis are solids. In a forensic science laboratory, routine methods of analysis such as spot tests and infrared spectroscopy (IR) (Bell *et al.*, 2012) are used initially to establish the type and number of drug(s) present in a specimen, such as heroin, cocaine, morphine or amphetamine. Combined, or hyphenated, techniques such as gas chromatography–mass spectrometry (GC-MS) and liquid chromatography–mass spectrometry (LC-MS) (Smith, 2005) and proton nuclear magnetic resonance (NMR) (Hays, 2005) are used for quantification.

A considerable amount of work on the identification of explosives and gunshot residues by XRPD has been undertaken (Abel & Kemmey, 1975; Beveridge *et al.*, 1975; Beveridge, 2010; Canfield & De Forest, 1977; Wolten *et al.*, 1977; Tassa *et al.*, 1982). However, explosives and narcotics can also be detected and analysed by, amongst other techniques, Raman spectroscopy (Sands *et al.*, 1998; Lacey *et al.*, 1996; Hayward *et al.*, 1995; Cheng *et al.*, 1995; Bell *et al.*, 2012; López-López *et al.*, 2012) and by ion mobility spectrometry (IMS) (Lawrence, 1987; Eiceman *et al.*, 2007). Development of some of these methods has been driven by the need to analyse drugs and explosives on site, at airports and seaports, without having to bring samples to a laboratory. Inorganic gunshot residues (primer residues) are normally analysed by scanning electron microscopy coupled with energy-dispersive spectrometry (SEM-EDS) (Wolten *et al.*, 1977), while organic residues (propellants) are analysed by chromatographic techniques (Lloyd, 1983; Laza *et al.*, 2007).

Techniques for examining paint flakes include visible light microscopy (Hamer, 1982), chemical tests (Castle, 1982) and SEM-EDS (Henson & Jergovich, 2001). Vehicle paint analysis in most laboratories is now undertaken using Fourier transform infrared spectroscopy (FTIR) because of the availability of comprehensive databases of automobile paint infrared spectra, one in North America known as PDQ (Paint Data Query) (Beveridge *et al.*, 2001), and one in Europe, known as EUCAP (European Collection of Automotive Paints). Use of these databases will not identify paint from one specific vehicle, but will narrow down the search to a manufacturer, a model and a year. Plastics and polymers can be identified by infrared spectroscopy (Heilman, 1960) and NMR, while metals and alloys are most readily analysed by XRF and SEM-EDS.

For particle identification, visible light microscopy used in conjunction with the McCrone *Particle Atlas* (McCrone & Delly, 1973) is a very useful alternative approach. Speed of analysis can be a critical factor, as can fitness for purpose, bearing in mind that XRPD provides information about the *compounds* present, and not just about the elemental composition.

7.2.2. Instrumentation

7.2.2.1. *Choice of instrumentation*

7.2.2.1.1. *Reflection or transmission diffractometry*

Most forensic science laboratories, if they have XRPD equipment, will have a powder diffractometer capable of operating in reflection or transmission mode, or both (Klug & Alexander, 1974; Jenkins & Snyder, 1996). Individual analysts may have a preference for one mode or the other, but it is wise to be familiar with the operation of both, as each has its own advantages and disadvantages. The correct choice of instrument for a given specimen is a matter of experience and also a reflection of the analyst's understanding of the equipment's capabilities. If a suspect specimen is very small, it must be compared with a control specimen of similar size. One should never compare the diffraction patterns of a small suspect specimen with that of a large control specimen, even if a considerable amount of control is available. A small specimen (a paint flake, a speck of unknown material, a sub-milligramme quantity of powder, scrapings from a surface, a sliver of metal) should be mounted as for transmission diffractometry, and larger quantities of powder, paper specimens and flat metallic specimens are ideal candidates for reflection geometry. Some small specimens may be analysed in reflection mode, but only if they are mounted on a zero-background substrate and appropriate small slits are selected.

7.2.2.1.2. *Scanning detector or stationary position-sensitive detector (PSD)*

Conventional powder diffractometers have detectors that scan at predetermined rates through an angular range selected by the analyst, and thus collect data sequentially. Stationary position-sensitive detectors amass the data over a fixed angular range, but simultaneously, resulting in rapid acquisition of data. This can be advantageous if, for example, the specimen is unstable, sensitive to light or to moisture, but one disadvantage of the PSD is that its angular resolution tends to be inferior to that of a scanning detector equipped with narrow receiving slits.

7.2.2.1.3. *One-dimensional or two-dimensional detector*

A further choice can be made, and that is to select a diffractometer that has a two-dimensional area detector (He, 2009), instead of the more common one-dimensional detector. Again, this choice will depend upon the type of specimen under examination – and one's budget, because two-dimensional detectors tend to be more expensive. The two-dimensional powder pattern generated can be much more informative in terms of crystallite size and preferred orientation effects than a one-dimensional pattern generated by a conventional reflection-geometry diffractometer.

7.2.2.1.4. *Energy dispersive X-ray diffraction (EDXRD)*

Energy dispersive X-ray diffraction, sometimes referred to as coherent X-ray scattering (CXRS), is an alternative to the usual angle-dispersive X-ray diffraction mode, in which a sample is irradiated with polychromatic white X-rays at a fixed scattering angle. An energy-dispersive detector is used to detect the wavelength of the scattered X-rays (Cook *et al.*, 2007; Sun *et al.*, 2010). Unlike conventional angle-dispersive XRPD equipment, it has no moving parts and it is a low-resolution technique that has its uses where a fixed geometry with penetrating X-rays is required, for example at luggage inspection facilities at airports and seaports (Harding & Harding, 2007). It would not be used in a forensic science laboratory for analysis of evidence, but more as a high-throughput screening technique to identify materials such as explosives and drugs concealed within items of luggage. Its chief disadvantage is the poor energy resolution obtained due to the limited energy resolution of the detector.

7.2.2.1.5. *Focal construct geometry*

An alternative to energy-dispersive X-ray diffraction for screening purposes is so-called focal construct XRPD. This comprises a simple novel geometry (Rogers, Evans *et al.*, 2010; Prokopiou *et al.*, 2014; Dicken *et al.*, 2014) that enables the measurement of diffractograms from polycrystalline materials through *linear translation* of a point detector. It is an angle-dispersive arrangement that is directed towards maximizing diffraction intensity at a measurement point, and has potential use as an alternative means of screening packages for illicit materials. The concept has been extended to the discrimination of liquids, in which a variety of liquids relevant to security inspection was analysed by focal construct technology, enabling discrimination of potential threat liquids (Prokopiou *et al.*, 2013).

7.2.2.2. *Choice of radiation*

The first choice in most laboratories would be Cu $K\alpha$ radiation (1.5418 Å), but if a large number of specimens are known to contain iron, iron oxides or salts of iron, Co $K\alpha$ radiation (1.7903 Å) should be used to remove the nuisance of fluorescent radiation, unless a diffracted-beam monochromator is fitted. Cobalt radiation represents an acceptable compromise between copper and chromium (2.291 Å) radiation. Unlike chromium radiation, which requires a vacuum, it is energetic enough to overcome absorption by the air. Its longer wavelength, relative to copper radiation, improves dispersion, enabling the resolution of low-angle diffraction peaks produced by organic specimens. With EDXRD used in its imaging capacity to locate and analyse materials concealed within baggage at ports of entry, radiation of higher energy is required. Items of baggage are examined in transmission mode, and incident-beam accelerating voltages tend to be of the order of 150 kV or higher (Harding & Harding, 2007; Dicken, Evans *et al.*, 2015; Dicken, Shevchuk *et al.*, 2015).

7.2.3. Technical procedures

7.2.3.1. *Variety and types of specimen encountered and specimen preparation*

In theory, any substance could be a forensic sample. A fundamental requirement for XRPD is that it must be crystalline, or something containing a crystalline substance. The following are some of the substances encountered in forensic casework: minerals, metals and alloys, paints, cosmetics, ointments, drugs and their excipients, papers, safe ballasts, detergents, pigments and dyes, plastics and polymers, abrasives, explosives, gunshot residues, soils, gemstones, automobile underseals, and building materials – plasters, putties, bricks, cements, mortars and concrete.

Specimen preparation for forensic analysis means disturbing the specimen as little as possible. Each sample should be treated on its merits and on the circumstances of its origin. It is good practice to examine the sample first using a low-power visible-light microscope to observe its physical characteristics. For example, if it is a powder, does it contain more than one component, is it contaminated, does its texture tell you anything? If it is a paint flake, how many layers are visible, are they coloured differently, can they be separated with ease? Do the nature and circumstances of the case dictate the way in which you should treat the sample? Is identification required, or merely a comparison of diffraction patterns? How much sample is available for analysis? Is non-destructive analysis absolutely essential, is the specimen required for other analytical techniques – if so, what is the best way of mounting the specimen?

7.2.3.2. *Specimen preparation – powders*

A good general reference for specimen preparation is that of Buhrke *et al.* (1998). Most routine diffraction work on powdered specimens is done in reflection mode. Each instrument manufacturer provides their own specimen holders, consisting of metallic discs with circular depressions machined to different depths to accommodate varying amounts of specimen. Other discs, known as zero-background holders (ZBHs), are made of a slice of silicon cut parallel to the 510 plane, which gives rise to no Bragg peaks in reflection mode. The sample is ground in an agate mortar, and is loaded into the metallic holders by top, back or by side loading (McMurdie *et al.*, 1986). Some silicon zero-background holders have a shallow depression machined in them, such that a small amount of powder may be loaded, but it is usual to take the flat surface, smear it with, *e.g.*, petroleum jelly, wipe it with a tissue and then sprinkle the small amount of the sample on the wiped surface. There will be sufficient adhesion to retain a thin layer of specimen after the excess is shaken off.

Specimens for transmission diffractometry may be mounted in one of three ways: as a thin planar specimen trapped between, *e.g.*, two polymer Kapton foils (8 µm; Spex-Certiprep, Stanmore, UK), or as a Debye–Scherrer cylindrical specimen in either a capillary tube, or as a minute specimen stuck on the end of a glass fibre with an adhesive such as rubber solution. The following procedure applies equally to organic and inorganic materials, with the exception of explosives, very hard abrasives, gemstones and single crystals, which for one reason or another should not be ground up: the coarse powdered sample is ground in a small agate mortar until the particle size is such that the resulting fine powder can be loaded easily into a 0.3 or 0.5 mm-diameter thin-walled glass capillary tube or sandwiched between Kapton foils. The foils are clamped between two metal rings, with a circular specimen aperture of typically 6 mm diameter. The specimen holder is spun in its own plane, which is presented perpendicular to the X-ray beam. For the Debye–Scherrer specimen, the filled tube is sealed with a flame and then mounted in modelling clay on a brass stub that fits in a standard ACA thread goniometer head, or on any stage suitable for the chosen diffractometer. The rod-like specimen is rotated about its long axis.

Large quantities (kilogrammes) of powder need to be sampled and subsampled prior to analysis, and the best way to ensure that the analytical specimen is truly representative of the bulk is to use a technique known as 'cone and quartering' (Buhrke *et al.*, 1998).

For microsamples of powder, for example those less than 1 mg in weight, a different approach may be used. The sample is carefully ground in an agate mortar as before, then a glass fibre (~0.05–0.1 mm in diameter) is dipped lightly in rubber solution and the end bearing the glue is rolled in the finely ground powder. The powder specimen is thus presented to the X-ray beam as a small-diameter cylinder. The main disadvantage here is that the beam has to pass through the adhesive and glass fibre as well as the specimen. Alternatively, a tiny ball of rubber solution (~0.5 mm diameter) can be rolled around in the powder with a needle, and the ball then speared with a thin glass fibre and mounted on the specimen stage. The glass fibre is rotated about its long axis as before.

Data are collected over an angular range appropriate to the specimen and radiation, in steps of 0.01–0.05° in 2θ.

7.2.3.3. *Specimen preparation – metals and alloys*

If the metallic specimen is of suitable dimensions, it may be placed directly on the sample stage of the diffractometer. If analysis of a large block of metal is required, a small sliver or a few filings will have to be removed, with a sharp scalpel or a clean needle file, respectively. One alloy, brass, is very common, and it occurs occasionally as a forensic sample (Rendle, 1981). Most metallic specimens need to be annealed before analysis, two common exceptions being aluminium and lead because, as relatively soft metals, any strains in them are quickly relieved at room temperature. Filings and slivers of brass, however, do require annealing in order to relieve strains within the specimen. This process ensures sharp, well defined diffraction peaks, enabling the measurement of accurate *d*-spacings. The tip of a glass Pasteur pipette is sealed in a Bunsen burner flame and the slivers or filings poured into the pipette. The part of the pipette containing the sliver or filings is then broken off and its open end sealed in a flame. The sealed tube is heated in a furnace to 773 K and slow-cooled to room temperature over 12–15 h. The sealed tube is removed from the furnace and broken open. The annealed sample is then poured out of the pipette, and the specimen, if filings, is sealed inside a thin-walled glass capillary tube as for a powder, or, if a sliver, is mounted on the end of a glass fibre with rubber solution, as for a paint flake, and placed on a diffractometer goniometer head or an equivalent sample spinner.

7.2.3.4. *Specimen preparation – monolithic (polycrystalline)*

A paint flake is a monolithic specimen, and usually consists of crystalline pigments and extenders (bulking agents such as talc and china clay) embedded in an amorphous resin. If the paint flake is multilayered, the layers can be separated and analysed individually, or analysed *in situ* if the X-ray beam is of a suitably small dimension (Kügler, 2003), otherwise the components identified by XRPD cannot be assigned to a specific layer. A glass fibre 0.05–0.1 mm in diameter is mounted in modelling clay on a brass stub. The end of the fibre is dipped lightly in rubber solution to leave a tiny deposit on the end of the fibre. The paint flake is picked up on the glued end of the fibre and teased into place with a needle probe so that it stands up on the tip of the fibre. If the flake is required for further analysis, such as analysis of the resins by pyrolysis–mass spectrometry (PyMS), water-soluble glue such as gum arabic should be used instead of rubber solution, so that the paint flake can be washed with water and removed from the fibre after XRPD analysis and prior to PyMS.

Other monolithic specimens are papers, plastics and polymers, and metallic slivers. Small specimens of these materials may be mounted and analysed by the same method as that described for paint flakes. Larger specimens of paper (Foner & Adan, 1983) may be mounted on aluminium mesh or a silicon ZBH using a suitable spray-mount adhesive. The substrate with the specimen is then placed directly in the diffractometer.

7.2.3.5. *Sample preparation – single crystal*

Single crystals of material that cannot, or should not, for a variety of reasons, be ground up are usually analysed in Gandolfi mode (Gandolfi, 1967). The reason could be that the crystal is explosive, too hard to grind (an abrasive material), too valuable (a gemstone), liable to change its crystalline form (polymorphism), or that its evidential value as a single crystal would be lost if it were crushed. XRPD data collected by a traditional point detector (one-dimensional) would not enable identification, and even data from a two-dimensional area detector may be difficult to interpret. Gandolfi mode, with its extra degree of rotational freedom for the specimen, generates a pseudo-powder pattern from a single-crystal specimen. The crystal (usually no larger than 0.5 mm in dimension) is mounted on the tip of a fine glass fibre (as for paint flakes) and placed on the Gandolfi stage.

In the case of gemstones it may be possible, if the stone has a fairly sharp culet, to mount it directly on modelling clay such that the culet just enters the X-ray beam. Powders such as barbiturates exist in many polymorphic forms, and it is known that some forms transform upon grinding into other crystalline modifications. A powdered barbiturate can be loaded directly (without grinding) into a thin-walled capillary tube, and the tube centred on the Gandolfi stage.

7.2.3.6. *Interpretation of results: identifications and comparisons, checking procedures*

When the samples have been submitted, together with details of the case circumstances, and the forensic diffractionist has collected all the diffraction data, he or she is then faced with interpreting the results. Most instrument manufacturers provide a copy of a database of powder patterns such as the ICDD Powder Diffraction File (ICDD, 2014) with their equipment, and appropriate data processing and search/match software, with some allowing the local user to input their own data collected from pure certified standard materials. This is a useful option, particularly where a lot of the submitted samples are of the same type and similar compositions are encountered on a frequent basis.

Many interpretations will be straightforward, with every diffraction peak in a pattern accounted for, but for every simple interpretation there will be at least two that are not easy, with unassigned or diffuse data. This is where additional information is often useful, for example the colour and/or the elemental composition of the specimen. The Boolean logic capabilities of the Powder Diffraction File enable one to incorporate such information within the search/match procedure. A successful, correct interpretation will depend upon the quality of the diffraction data, the interpretative skills and experience of the analyst, and also on the content and reliability of any databases that are used. It is incumbent on the analyst to ensure the quality of diffraction data by careful and consistent (in the case of control and suspect) specimen preparation, by choosing the most appropriate mode of diffractometer analysis, and by correct choice of instrumental parameters, *e.g.* radiation, filters/monochromators, slit size, beam collimator diameter, scan range, scan rate and step size. All interpretations should be checked by a second competent individual, preferably another diffractionist, before a technical report is produced. Quantitative analysis is possible on some specimens, but should be applied with caution. Forensic samples are rarely found as homogeneous and well ground powdered materials, with each component having similar particle size, no evidence of preferred orientation and similar absorption coefficients. Various methods of quantitative XRPD analysis, including Rietveld methods, are discussed by Madsen & Scarlett (2008).

7.2.3.6.1. *Use of the ICDD Powder Diffraction File and local databases*

The ICDD Powder Diffraction File (ICDD, 2014), produced and marketed by the International Centre for Diffraction Data, is recognized as *the* primary database for powder diffraction data. Both PDF-4+ (primarily inorganic) and PDF-4 Organics files are essential if powder diffraction analysis is to be one of the major analytical techniques used in a forensic science laboratory. The PDF contains within it a ‘forensic’ subfile, comprising approximately 4500 entries, of the patterns of compounds thought to be most relevant.

Most X-ray sections within forensic science laboratories will have their own local databases, usually built up over a period of time, when it becomes apparent what the most frequently encountered substances are. The laboratory must be careful to obtain pure, accredited specimens whose chemical composition is proven for producing standard diffraction patterns in-house. A specialized database of the powder patterns of forensically relevant substances complete with a search/match routine (Fischer & Goebel, 1984) was produced in 1984.

The most rapid and efficient approach is to use the locally generated standard powder patterns first, followed by the PDF forensic subfile, and then finally the whole PDF if there are still diffraction peaks unaccounted for.

7.2.3.7. *Data archives for statistical and reference purposes*

Once the interpretation has been completed and checked, and the report or statement written, the matter of filing and archiving the analytical results remains. The retention of case files, with all their information, is at the discretion of the local judicial system, and the seriousness of the crime will usually dictate the length of time for which the files are kept. Digital diffraction data tend to be archived automatically by the commercial software, but the retention of analytical interpretations will be a matter of local preference. It is a relatively simple task to set up and populate a spreadsheet with analytical results obtained from, for example, paint analyses or drug analyses, updating the spreadsheet at regular intervals, and this practice is highly recommended. In this way a useful reference system can be built up, and the data can be classified and cross-referenced in different ways. For example, paints can be classified as household, automobile, tool, security, each in terms of its colour. The household paints can be classified further as emulsion or enamel, gloss, undercoat or primer. Automobile paints can be listed under metallic or non-metallic finish. All paints can be re-classified according to their pigments, fillers and extenders.

Recording the results of drug analyses is of greatest benefit when the excipients, adulterants or impurities such as precursors and by-products of attempted syntheses are also included. A database of this kind may be searched easily and quickly, identifying mixtures of similar composition, possibly indicating a common source and providing, in a simple way, drugs intelligence. Powder diffraction patterns of prescription or over-the-counter drugs can be useful in identifying formulations. Paint flakes found on the clothing of the victim of a hit-and-run

Table 7.2.1
Statistics generated from a decade of drug analysis by XRPD

(*a*) Relative percentages of drug types analysed by XRPD over a period of ten years.

Drug	1980	1989
Heroin base	7	31
Heroin·HCl·H_2O	26	<1
Cocaine·HCl	21	29
Cocaine base	2	4
DL-Amphetamine sulfate	37	34
D- or L-Amphetamine sulfate	4	<1
Others	3	2

(*b*) Percentage of amphetamine, heroin base and cocaine·HCl seizures containing one or more of the carbohydrate excipients glucose, mannitol, lactose and sucrose analysed by XRPD over the period 1980–1989.

Drug	Glucose	Mannitol	Lactose	Sucrose
Amphetamine	87	46	10	2
Heroin base	23	12	2	1
Cocaine·HCl	42	35	15	<1

automobile accident can often lead, on forensic analysis and with the co-operation of the major automobile manufacturers, to the make, model and year of the car involved.

Household, garage or garden chemicals may be used in the commission of a crime, and it is of help to purchase quantities of the genuine articles as control samples and to acquire their powder diffraction patterns. These data will then form part of another database.

Keeping records of the type described can be very useful over a long period of time. Trends in drug usage may be revealed, together with trends in the use of excipients and adulterants (Table 7.2.1). Declining use of one drug may be counterbalanced by a rise in use of another (Rendle, 2004). Paint analyses may reveal a gradual replacement of older inorganic pigments by more modern organic pigments (Susich, 1950; Kamarchik, 1980; Curry *et al.*, 1982). Extenders and fillers in paints may change for economic reasons. Statistics like this, however simple, all serve as very useful background information for a court-going scientist.

7.2.3.8. *Continuity of evidence*

The chain of custody, evidentiary chain, or continuity of evidence is a crucial aspect of any forensic process. Items of evidence are submitted to the laboratory, in sealed, labelled exhibit bags, following strict rules in order to preserve the integrity of the items and their admissibility in court. Records of items requiring any chemical analysis must be kept in such a way that the movement and location of any item can be followed by an audit trail. Diffraction patterns must be labelled electronically such that they can be associated with one, and only one, specimen. Any samples submitted for analysis should be signed for, in the presence of the person who requests the analysis, and kept in a secure location until the analysis is complete. If the forensic science laboratory has a laboratory information management system (LIMS) that employs barcoding, then each new sample brought into the X-ray laboratory will be assigned a unique barcode which will remain with that sample and act as its identifier throughout the entire analytical process. Such systems can be expensive, however, and many laboratories still rely upon manual computer entries. This requires diligence on the part of staff, and rigorous adherence to protocol in order to prevent errors that may then be propagated through the evidentiary chain. It is perfectly within the right of the court to insist on seeing a printout of the laboratory logbook, in order to be convinced of the integrity of the whole analytical process.

Particular care is needed if the X-ray diffractometer has an automatic sample changer which has to be loaded manually, and in which a specific sample *must* be placed in a specific location. If a barcode system is in place then the likelihood of errors here is less, because the controlling software will detect a mismatch between the sample barcode and the barcode of its position on the holder. If manual loading is the norm, then each loading process should be witnessed by another X-ray diffractionist, and the signatures of both recorded as confirmation.

Continuity can be aided by removing one stage of the process, and that is by 'through the bag analysis'. Powdered materials, such as suspected illicit drugs, may be analysed, under certain circumstances, by diffractometry without removing the powder from its packaging (Rogers, 2012) (Fig. 7.2.1).

7.2.3.9. *Presentation of evidence to the court*

Procedures will vary from country to country, but in general the scientist can be expected to be questioned quite thoroughly by a well briefed counsel (Camp, 1979). The witness's academic and professional qualifications, or lack of them, are tackled first, thus establishing his or her credibility. Then counsel may ask how long they have worked as a forensic scientist and for how long in X-ray diffraction. Reference to the items analysed by XRPD follows, and the diffractionist may be asked to explain to the court, in layman's terms, how XRPD works. It is important to avoid scientific jargon, and development of a simple analogy is often the best approach.

Continuity of evidence will most certainly be questioned, with the analyst being asked if he or she is sure that the analytical results being reported are indeed those from the specimens submitted for analysis. Adherence to published quality-assurance procedures will also be queried. This will cover all specimen preparation procedures, the correct use of the X-ray instrument used for the analysis, correct computer entry of specimen details, unique labelling of diffraction patterns, and interpretation of the results. Any deviation from the laboratory's own published procedures, without very good reason, will be noted and used to undermine the validity of the work. The scientist may be asked to provide proof of validation of the XRPD method used in their laboratory, according to internationally recognized standards (Eckardt *et al.*, 2012).

Having got thus far, the diffractionist will be questioned on the results obtained from X-ray analysis of the evidential items, and the depth of questioning will depend upon whether or not counsel has a diffractionist briefing him or her. Questions on the suitability of XRPD for the analysis of the samples may be raised, and the analyst may be asked why he or she did not use another technique. It is here that the analyst must be aware of the alternative methods of analysis, and their pros and cons. As an expert witness, the analyst will usually be permitted to qualify his or her statements, and not be restricted to yes/no answers. The source of standard diffraction data may be queried, and it is advantageous to be able to say that one has used the most up-to-date database, such as the ICDD Powder Diffraction File (ICDD, 2014), in one's interpretations.

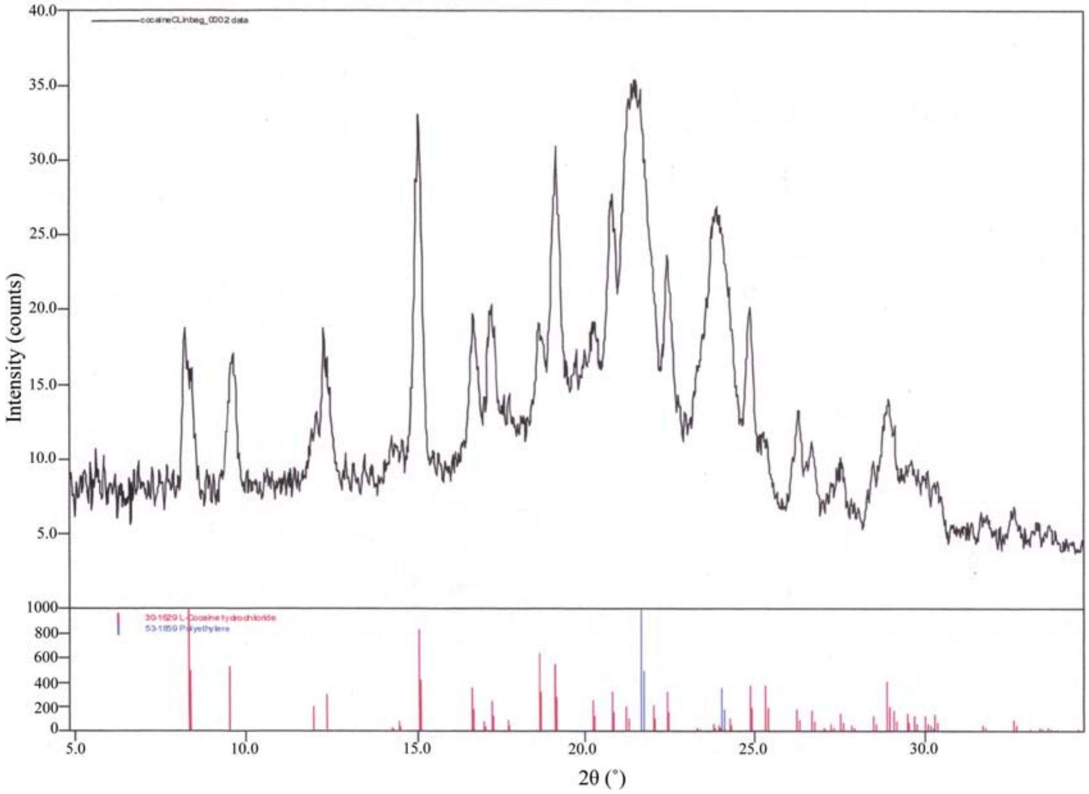

Figure 7.2.1
A powder pattern of cocaine hydrochloride (PDF No. 00-030-1629; red peaks in lower plot) acquired through a polyethylene bag (PDF No. 00-053-1859; blue peaks in lower plot). The pattern was acquired in 60 s using a Bruker D8 GADDS two-dimensional detector.

7.2.4. Examples of forensic casework involving the use of XRPD

7.2.4.1. *Criminal damage to an automobile*

A Porsche automobile belonging to a known criminal had been seized and impounded by the local police, pending charges against the man. However, evidence against the man was weak and charges were dropped. He was released and was allowed to reclaim his car. After a week he reported to the police that his car had gradually lost all power and he accused them of tampering with the engine.

The car was examined and oil from the sump was drained and filtered. A small amount of dark, very hard particles was found in the residue from the oil. A single particle was mounted on a glass fibre and rotated in Gandolfi mode using a Bruker D8 GADDS two-dimensional detector. Fig. 7.2.2 shows the particle, its two-dimensional XRPD pattern and its digitized pattern. The pattern is a match with that of silicon carbide (PDF No. 00-049-1428).

Under questioning, one of the police officers admitted to having removed the sparking plugs when the car was impounded, and to pouring valve grinding paste into the cylinders – hence the silicon carbide.

7.2.4.2. *Fatal road traffic accident*

A motorcyclist was killed in a head-on collision with an automobile. The driver of the car claimed that he had not seen the motorcyclist because he (the motorcyclist) had not had his headlight switched on. Other motorists who witnessed the accident said that the motorcyclist's headlight was definitely switched on.

Upon examining the motorcycle wreck, the headlamp bulb was found to be shattered. Microscopic examination of the bulb revealed traces of a pale yellow powder on the bulb filament and on the inside of the remains of the glass envelope. A very small amount of the powder was picked up with rubber solution on the end of a glass fibre and rotated in Debye–Scherrer mode using a

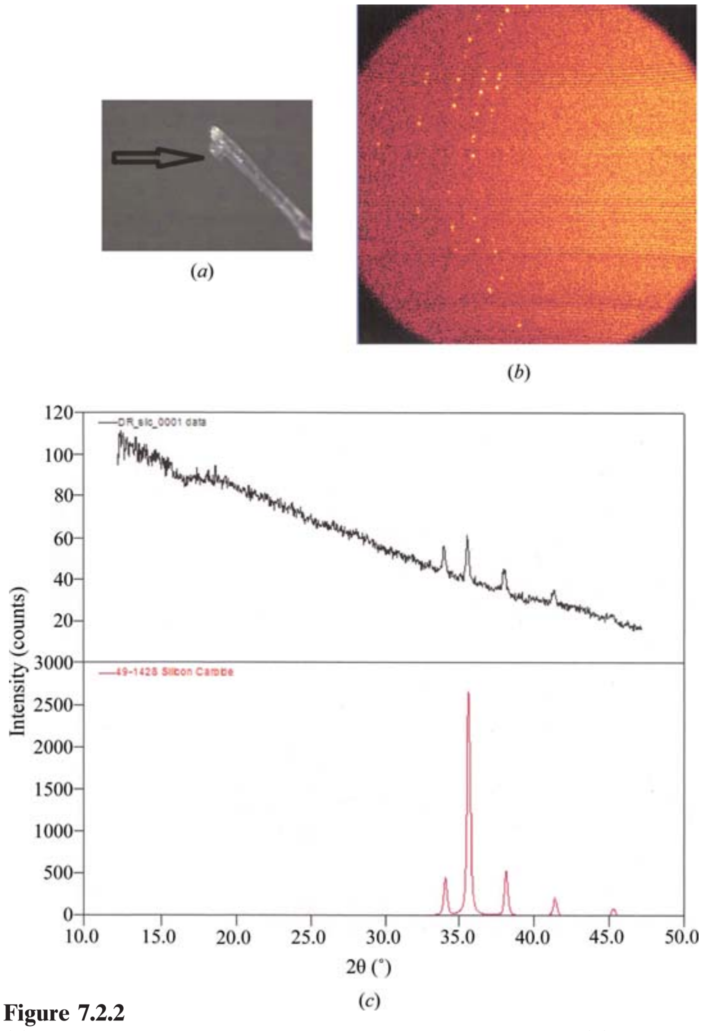

Figure 7.2.2
(*a*) A particle from vehicle oil mounted on a glass fibre, (*b*) the two-dimensional Gandolfi pattern and (*c*) the integrated digitized pattern (top) and PDF pattern (bottom) No. 00-49-1428 of silicon carbide (SiC).

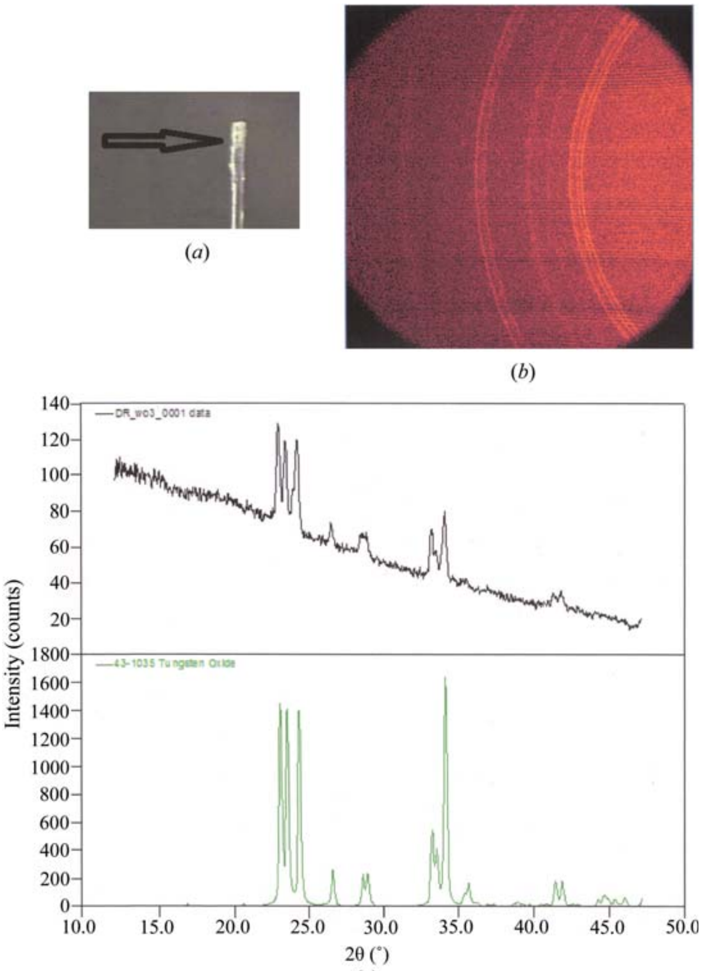

Figure 7.2.3
(*a*) Yellow powder particles glued to a glass fibre, (*b*) their two-dimensional Debye–Scherrer powder pattern and (*c*) the digitized powder pattern (top) and PDF pattern (bottom) No. 00-043-1035 of tungsten oxide (WO_3).

Bruker D8 GADDS two-dimensional detector. Fig. 7.2.3 shows the powder on the glass fibre, its two-dimensional XRPD pattern and its digitized pattern. The pattern is a match with that of tungsten oxide (WO_3) (PDF No. 00-043-1035).

The presence of tungsten oxide is proof that the headlight was switched on at the moment of impact. The tungsten filament was at white heat when the bulb was shattered and reacted with the oxygen in the atmosphere, forming tungsten oxide.

7.2.4.3. *Attempted murder?*

A young woman and her boyfriend had dinner together at his apartment. Later in the evening they argued and she went back to her own apartment, where she fell asleep. During the night she was violently ill and the next morning went to the local police station and accused her (now ex-) boyfriend of attempting to poison her. Samples of the food and wine consumed were collected by scenes-of-crime officers and sent for analysis. Two wine corks appeared to have some purplish solid residue and this was scraped off and ground thoroughly before examination by reflection geometry XRPD using a PANalytical X'Pert Pro diffractometer. A specimen was mounted for XRPD, and the result of a search/match using ICDD's PDF-4 Organics database was a match with the pattern for potassium bitartrate (PDF No. 02-075-1610).

This material is not poisonous. Tartaric acid occurs naturally in grapes and it reacts with potassium ions found in grape skins. Potassium bitartrate crystals are colourless ('wine diamonds') but can take on the colour of the wine. It would appear that the woman's illness had more to do with over-imbibing than to an attempt by her boyfriend to poison her.

7.2.4.4. *Synthesis of crack cocaine*

Crack cocaine is cocaine free base. It may be synthesised fairly simply by heating cocaine hydrochloride with sodium bicarbonate. If the synthesis is carried out carefully, the final products should be cocaine free base and sodium chloride. The presence of any additional compounds would indicate a poor synthesis.

A number of persons suspected of being in possession of controlled substances were arrested. All seizures were sent to the laboratory for analysis. Each produced a very similar powder diffraction pattern to the others, so the police had good reason to suspect that only one dealer was involved. One of the arrested gave information as to the location of the alleged dealer and the address was raided, a man taken into custody, and a large bag of white powder together with drugs paraphernalia taken for examination. Interpretation of the XRPD pattern of the powder from the suspected dealer's house, using the PDF-4+ database, revealed the presence of cocaine base (00-006-0153), sodium chloride (00-005-0628) and sodium bicarbonate (00-015-0700).

The composition of this powder was found to be very similar to those of each of the powders found on the people arrested. The presence of sodium bicarbonate indicated a rather careless synthesis, but in this instance its presence in both the stock supply, and in each of the individual seizures, constituted valuable information from a comparison viewpoint.

This evidence together with that supplied by other witnesses was sufficient to convict the dealer.

7.2.5. Summary

7.2.5.1. *Advantages and limitations of XRPD in forensic science*

The preceding paragraphs demonstrate that XRPD is a very useful technique to have for analysing solid materials that are either wholly or partially crystalline. Its advantages over some other analytical techniques are:

1. its ability to identify *compounds* rather than just elements or functional groups;
2. its non-destructive nature;
3. its versatility;
4. its ability to analyse mixtures of materials;
5. its ability to cope with microgramme to gramme-sized specimens, and single crystals;
6. its lack of need of special preparation for powder specimens – simple grinding is required;
7. its ability to distinguish polymorphs;
8. its ability to distinguish racemic materials from their optically active counterparts;
9. its ability to distinguish between a series of hydrated forms of a given compound; and
10. its ability to be both a qualitative and a quantitative method of analysis.

Disadvantages include the fact that one cannot analyse liquids or gases, and that XRPD is not generally a suitable technique for analysing amorphous materials, although there may be cases in which it can be useful. It is not a true trace technique; low levels of a substance in a mixture may go undetected.

The type or types of material one is called upon to analyse, and the kind of information desired, will dictate the analytical methods used, but if one is concerned mainly with solid specimens, XRPD has few rivals. In terms of cost, the original outlay for capital equipment items such as the X-ray generator and diffractometer can seem relatively high, but when one considers the expected lifetime of at least ten to fifteen years, it is very reasonable. Sealed X-ray tubes and specimen mounts are the main consumables, and neither liquid nitrogen nor liquid helium is required.

7.2.5.2. *Thoughts on the future*

The need for rapid results is a subject that is frequently raised at meetings between forensic scientists and the law-enforcement agencies they serve. As well as reducing turnaround times for laboratory analyses, the provision of scientific information *at the crime scene* can be extremely useful to the investigating officer. This is where truly portable equipment is required, and one such example provides both XRPD and XRF analysis on a 15 mg specimen (Inxitu, 2012). This device uses a microfocus X-ray tube with pinhole collimation and a solid-state CCD detector to acquire both the X-ray powder pattern and an XRF spectrum. Simultaneous acquisition of elemental composition helps narrow the range of compounds selected during a search/match procedure. A novel sample vibration chamber helps alleviate problems of preferred orientation within the specimen. Undoubtedly concerns will be raised as to the dangers of using X-rays at a crime scene, but the design of equipment such as that described above is such that there are no safety issues, as primary and scattered X-radiation are fully contained.

Miniaturization and portability of analytical equipment have long been goals both for forensic scientists and instrument manufacturers, and to a certain extent those goals have been achieved, but there is always a price to pay, and here it is in the quality of the resulting diffraction patterns. One should never expect the same quality of data from portable equipment as from laboratory-based diffractometers, but as long as the use of portable equipment is for quick identification purposes at a crime scene, for example, then this is quite acceptable. Equipment based upon energy-dispersive X-ray diffraction is an attractive option because of the absence of moving parts, but until solid-state detectors of suitable energy resolution are available, this mode of data collection will remain largely confined to that of screening duties.

There is currently sufficient variety in the design of laboratory powder diffractometers, which, with autosamplers and rapid data acquisition times, already guarantee fast turnaround times. There may be a demand for more two-dimensional area detectors in order to cope with minute powdered specimens or single crystals, and monolithic specimens exhibiting strong preferred orientation. Diffractometers capable of exploring the back-reflection region would be a useful addition, thus enabling accurate measurement of unit-cell parameters and hence discrimination between, for example, metallic specimens of closely similar composition, and solid solutions of minerals. Databases containing atomic coordinates, as well as powder patterns, for the most common materials will be sought after, as they would enable quantitative analysis by the Rietveld method for most specimens.

Most important of all, if a forensic science laboratory has XRPD equipment, retention of an XRPD expert is essential in order to maintain consistency in all aspects of the analytical process. Having a technician to maintain the instrument is essential, but the presence of an expert is needed for specimen preparation, choice of mode of analysis, interpretation of results and preparation of statements. The instrumental aspects of XRPD may become in time, as with many other analytical techniques, more 'black box' in nature, but the additional skills of an in-house expert will always be needed. Some laboratories may entertain the idea of providing a 'walk-up' service in XRPD, in which the person requesting the analysis is permitted to prepare the specimen themselves and mount it on the diffractometer, in order to economize on staff and time. This is false economy. It may be acceptable when the analytical technique is solution-based and the person has only to weigh out a specimen, dissolve it in solvent and place the solution in a vial (as for GC-MS). For XRPD analysis the practice should be discouraged for obvious reasons; specimen preparation is a crucial part of a successful analysis, and should be left to a full-time diffractionist.

The author wishes to acknowledge Professor K. D. Rogers and Dr S. Beckett for their helpful criticism during the preparation of this chapter. The comments and constructive suggestions made by the referees and the editors are also acknowledged.

7.3. Materials for energy storage and conversion

M. A. Rodriguez

7.3.1. Introduction

Effective and efficient means of energy storage and conversion are critical to the day-to-day operation and security of a modern society. Hence, research and development in this field continues to expand due to the demands for clean, robust and sustainable sources of energy. This chapter is devoted to the use of X-ray diffraction in the field of energy storage and conversion; the examples presented herein are meant to be demonstrative with regard to the various fields of research discussed. These fields include fossil fuel, hydrogen storage, wind, solar and battery technologies. The aim of this chapter is to give the reader a sense of the impact X-ray diffraction analysis can have on their research efforts in the field of energy-related materials and processes. Suitable references are given throughout the chapter to encourage further investigation on specific topics of interest to the reader.

7.3.2. Fossil fuel

While fossil fuels are discussed in more detail in Chapter 7.11, they are worth mentioning in this chapter concerning energy storage and conversion because coal/petrochemical sources supply a majority of the world's energy.

Coal is one of the most common and inexpensive sources of energy on the planet. It is also responsible for significant pollution and carbon emission. The use of powder X-ray diffraction (PXRD) characterization of coals from mining locations can yield significant information. Coal characteristics such as the fraction of amorphous carbon, the aromaticity and crystallite size can all be derived from standard XRD analysis (Lu *et al.*, 2001; Sonibare *et al.*, 2010). The aromaticity (or ratio of aliphatic to aromatic rings) dictates the rank of a given coal, which correlates to the overall carbon content and thereby energy potential of the fuel. XRD coupled with other techniques can be used in a straightforward manner to characterize coal and asphaltenes (see Yen *et al.*, 1961). In addition, XRD characterizes the mineral reactions that occur during the combustion of coal in power-plant boilers (Gupta, 2007). Such reactions are critical for the understanding of slagging and fouling composites.

While the solid-state technique of PXRD typically has little to say about liquid-based petroleum fuels, the science of diffraction plays a critical role in analysis of materials employed by the petroleum industry (see Chapter 4.6 on zeolites and Chapter 7.11 on the petrochemical industry). Herein we touch only briefly on the zeolite-enabled process known as fluid catalytic cracking (FCC) and the important role that the science of diffraction plays in this field. FCC is a mainstay of modern petrochemical refineries (Vermeiren & Gilson, 2009) and the zeolite structures employed in this process enable this critical technology for gasoline refining. The zeolite employed in this process, typically type Y of the faujasite (FAU) family, is the active component of the catalyst used for the hydrocarbon-cracking reaction. The acidic sites of the zeolite confined within a porous cage-like structure enable the preferential reactivity of the gas oil feed to yield gasoline (Vermeiren & Gilson, 2009). Zeolites are convenient because they can be tuned to form materials with specialized reactivity for specific catalytic applications. However, in order to understand these materials and their properties, the structures must first be fully elucidated. This is where PXRD has a major impact. Structures are typically determined by single-crystal X-ray diffraction analysis. However, single crystals of many zeolite compounds cannot be grown to sufficient size to obtain adequate single-crystal data sets for structure solution. The use of powder XRD coupled with Rietveld structure refinement (Larson & Von Dreele, 2000; Toby, 2001; Rodriguez-Carvajal, 1993) is routinely employed for structure analysis of these cage-like crystal structures. The location of exchanged cations and reaction sites within the framework can be the information necessary for predicting the properties and performance of these compounds (Scherzer, 1989). The demand for ever-improved processing of fossil fuels continues to drive research and development of catalytic zeolites and other framework compounds at an ever-greater pace (Corma *et al.*, 2002). The employment of XRD for structural characterization of these materials is a critical tool in this field. The reader is referred to Chapter 4.6 on zeolites for more details of these important structures.

7.3.3. Hydrogen storage

XRD also plays an important role in research and development of materials for hydrogen storage. Cage-like frameworks similar to zeolites, but where the cage is expanded through the use of large (typically organic) linker molecules, are being investigated as fuel-storage media. These metal-organic frameworks (MOFs) have been targeted specifically for hydrogen storage because they are capable of storing many times their weight in hydrogen (H_2), where the gas is loosely attached to adsorption sites within the molecule but can be extracted again as H_2 (typically through heating). Materials development of these compounds relies heavily on structural determination *via* PXRD. For example, Luo *et al.* (2008) describe an yttria-based MOF in which the metal centres are linked by 1,3,5-benzenetricarboxylate molecules to generate a very large cage-like structure, preferentially suitable to H_2 storage. The authors demonstrate the use of Rietveld refinement from powder diffraction data coupled with difference-Fourier analysis to illuminate the H_2 gas adsorption sites within the framework. As hydrogen only scatters X-rays very weakly, D_2 was employed as the adsorption gas and neutron diffraction analysis was performed for H_2 molecule location within the MOF. Deuteration coupled with neutron scattering is common practice for the determination of hydrogen-bearing compounds. Other elegant studies of hydrogen-storage materials have been performed. For example, Riktor *et al.* (2007) employed synchrotron radiation to analyse release of H_2 gas from the compound $Ca(BH_4)_2$. The high brilliance of synchrotron radiation is amenable to *in situ* studies, which are able to collect data with sufficient speed and resolution to capture reaction behaviour (*e.g.* phase transitions and thermal decomposition) with incredible detail. Riktor *et al.* (2007), showed that the H_2 gas

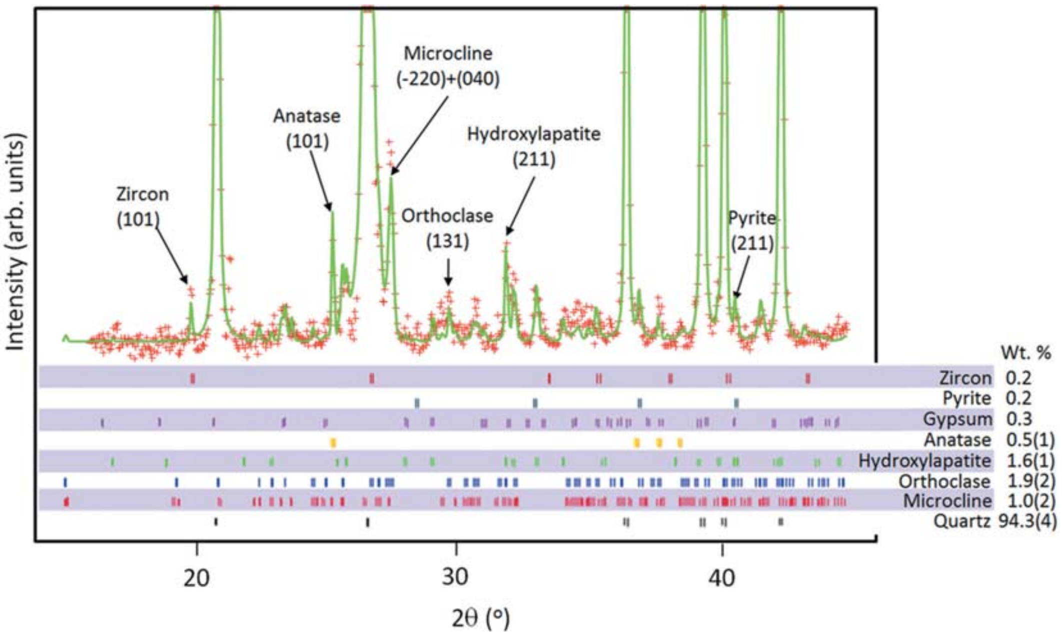

Figure 7.3.1
Multi-phase Rietveld refinement of a borehole specimen. The line shows the calculated pattern. Raw data points are shown as + symbols. Individual peaks for the trace phases are highlighted by arrows. Off-scale peaks are from quartz. Reflection tick marks for each phase are shown below the pattern. Quantitative weight % values for the phases are listed on the lower right of the plot. release initiated upon conversion of the low-temperature γ-Ca(BH$_4$)$_2$ phase to the high temperature β-Ca(BH$_4$)$_2$ phase. Synchrotron sources also have the advantage of a tunable X-ray wavelength and are therefore not restricted to a fixed wavelength as dictated by the anode of a standard sealed-tube source. In this regard, synchrotron sources are often employed for atomic pair distribution function (PDF) analysis. This is because synchrotron sources can easily generate the hard X-ray wavelengths (*e.g.* <0.5 Å) that are necessary to achieve high momentum-transfer values (*i.e.* $Q_{\max} > 20$ Å^{-1}) in measured data sets (see Chupas *et al.*, 2003). PDF data are useful for characterizing nearest-neighbour distances between atomic species in a structure and can be beneficial for both crystalline and non-crystalline compounds. Chupas *et al.* (2007) demonstrated the use of synchrotron radiation to detect the presence of H_2 in $Mn_3[Co(CN)_6]_2 \cdot 3H_2$ by differential PDF analysis. This approach revealed how the H_2 molecules are bound within the porous framework, resulting in a more detailed understanding of how H_2 is stored and recovered from the material. While access to synchrotron facilities is often limited, well designed experiments can lead to significant knowledge of a material's behaviour. Chapter 2.2 in this volume is dedicated to synchrotron radiation and the reader is referred to that chapter for further details.

7.3.4. Wind

One of the critical aspects of green technologies such as wind and solar is the intermittent nature of the harvested energy, which dictates the necessity for energy storage. Wind farms have been employing a clever strategy for power storage through the use of compressed air energy storage (CAES), as outlined by Cavallo (2007). This method employs the use of underground caverns (man-made or naturally occurring). When the wind is active at a time of low power demand, a wind farm may choose to transfer power to an air compressor that pumps air into a cavern, thereby storing the energy in the form of pressure. The energy can be converted back to electricity by releasing the air pressure through a turbine. Careful characterization of cavern geology is important, especially with regard to the materials present in the access boreholes that are drilled deep into the ground to bridge the cavern to the surface (Rodriguez *et al.*, 2012). Quantitative characterization of the phases present as a function of depth is important information for assessing the impact of cyclic air pressure on the CAES station. Fig. 7.3.1 shows a Rietveld refinement for an eight-phase diffraction pattern obtained from a core-drill specimen. The identification of the phases was facilitated by employing X-ray fluorescence (XRF) for determination of the elemental composition (Rodriguez *et al.*, 2012). It is worth noting that the plot in Fig. 7.3.1 shows intensity for phases that are very close to the background level. The quartz peaks, which make up more than 90 wt% of the sample, go off-scale on the intensity axis. This allows the signals from the other minor or trace phases present to be seen more easily. One phase of critical importance for CAES functionality was FeS_2 (pyrite), because oxidation of this phase could alter the pH and mineralogy of the borehole. The phase analysis *via* Rietveld refinement revealed a very small weight fraction of pyrite at this borehole depth. In fact, the quantity was so small and confounded by peak overlap with other phases that its detection proved difficult without the supporting XRF analysis. Typical errors associated with phase quantification are in the 0.1 to 0.5 weight percent range, depending on the quality of the XRD data and the scattering behaviour of the quantified phase. This is one of the limitations of powder XRD. Detection and quantification of major, minor and trace phases *via* XRD analysis can give better insight into the functionality and possible issues that might impact CAES, a practical option for energy storage at large wind-farm facilities.

7.3.5. Solar

The challenge of solar technology is to efficiently convert photonic energy from sunlight into another form of energy, typically electricity. The solar cell is the quintessential building block of the industry, but materials science challenges still remain. The three best-known issues with photovoltaics are: (1) the influence of grain boundaries, (2) the electron affinity of

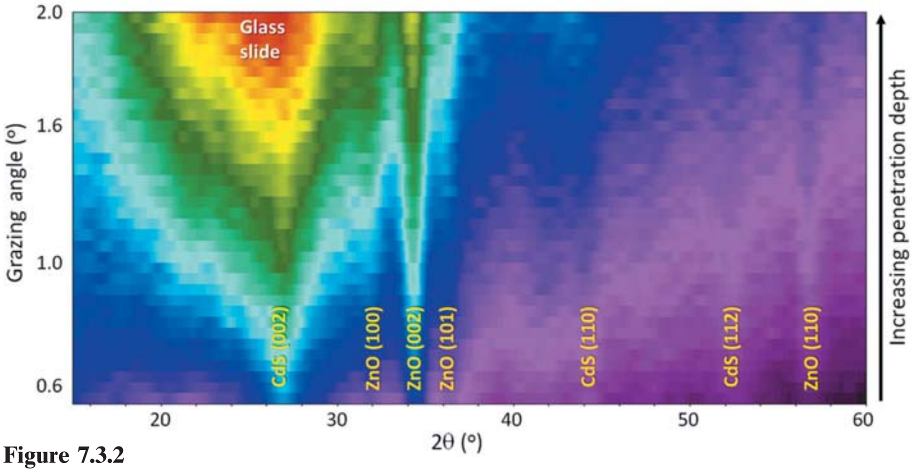

Figure 7.3.2
The GIXRD contour plot of a CdS/ZnO film deposited on a glass substrate. Increased grazing angle illustrates deeper penetration depth *via* detection of the broad amorphous peak from the substrate. (Data source: internal Sandia research, unpublished.)

absorbers and (3) the lack of clear understanding of point defects (Durose *et al.*, 2004). The fact that typical photovoltaic devices are of a thin-film nature often leads to analysis using grazing incidence X-ray diffraction (GIXRD) measurements (McCandless & Dobson, 2004; see also Chapter 5.4). GIXRD employs an 'asymmetric' diffraction condition where the film sample surface is set and fixed at a 'grazing angle' (GI) relative to the direct beam. GI values typically fall between 0.5 and 2° 2θ for Cu $K\alpha$ radiation and narrow-slit and/or parallel-beam optics are employed to reduce divergence. In this configuration, only the detector is scanned through the 2θ angle. The GI geometry enables preferential scattering from the film surface, thereby reducing the impact of the substrate. The benefit of GIXRD is offset by the difficulty posed by some samples that display significant preferential orientation. The assumption of a random grain distribution of the specimen guarantees that some of the crystallites will be in a diffraction condition for a given d-spacing of that phase, even when the grains must be *tilted* from the surface normal. When strong preferential orientation is present, this criterion breaks down. Fortunately, for many of the new nanomaterials being employed in solar cells, random orientation is more likely than for larger grained materials. Fig. 7.3.2 shows a series of diffraction patterns for CdS obtained using GIXRD. The CdS has been deposited as a film along with ZnO nanocrystallites upon a glass substrate. This contour plot shows 2θ on the x axis and incremental grazing angles on the y axis. Intensity, shown as a rainbow colour scale (purple = low counts, red = high counts), highlights the diffraction peaks as increasing intensity profiles with increased GI angle (*i.e.* penetration depth). Hence, this plot yields a qualitative depth profile for the film. The CdS (002) and ZnO (002) peaks are clearly detectable above the background level in this contour plot, especially at the lower GI angles; other peaks for these two phases are also observed. One can see the increase in the amorphous signal (broad peak centred at ~25° 2θ) when scans reach the higher GI angles (~1.6 to 2.0°). This indicates significant scatter from the glass substrate below the thin CdS film. Since the crystallite size-broadened nanocrystalline CdS (002) peak is significantly convoluted with the amorphous intensity from the glass substrate, a GI scan series can be of considerable help in discerning the CdS (002) peak presence in the sample. This is because one can look for the preferential detection of the surface film at lower GI angles, and then view this in context of the ever-increasing scatter from the glass as the GI angle increases. This adds confidence to the film detection.

Solar energy can also be employed for the cracking of CO_2 gas, to form CO and O_2. The subsequently synthesized CO gas can then be processed into hydrocarbon fuels *via* established syngas chemistry (Miller *et al.*, 2008). The high-temperature catalytic CO_2 cracking reactions are performed through a two-step electrochemical cycle that employs a reaction chamber where CO_2 gas can be exposed to an oxygen-starved material. One such material is an iron-doped zirconia ceramic (Coker *et al.*, 2012). The ceramic, isolated within the reaction chamber, can be heated *via* focused sunlight through a window on the reaction chamber (Miller *et al.*, 2008). At high temperatures (> 1473 K), Fe^{III} is reduced to Fe^{II} in the ceramic. The ceramic can then be cooled in an inert atmosphere to ~1373 K where CO_2 gas is bled into the chamber, re-oxidizing the ceramic by stripping the CO_2 of one of its oxygen atoms. This reactor system has been demonstrated in principle; however, understanding the science within the iron-doped zirconia ceramic has proven to be a challenge. The exact nature of the iron within the zirconia appears to influence the performance of the reactor. *In situ* high-temperature XRD has been performed in a mock reactor environment to monitor the changes in the zirconia catalyst material during heating and cooling in an inert atmosphere (Coker *et al.*, 2012). It is well known that Fe has a finite solubility in cubic ZrO_2 where the Fe may substitute at the Zr sites in the crystal structure (Davison *et al.*, 1988; Raming *et al.*, 2002). Iron substitution typically causes the cubic zirconia cell to contract. The use of *in situ* high-temperature PXRD has enabled the monitoring of an iron-saturated yttria-stabilized ZrO_2 (YSZ). Fig. 7.3.3 shows how the lattice parameter of this compound varies with heat treatment under an inert atmosphere (flowing helium). This sample was initially synthesized in air at 1773 K. There was a trace of haematite (Fe_2O_3) remaining in the powder, but the balance refined well as a cubic ZrO_2 with an initial room-temperature lattice parameter of a = 5.110 (3) Å. When *in situ* high-temperature PXRD was performed on this powder, typical linear thermal expansion behaviour occurs up to

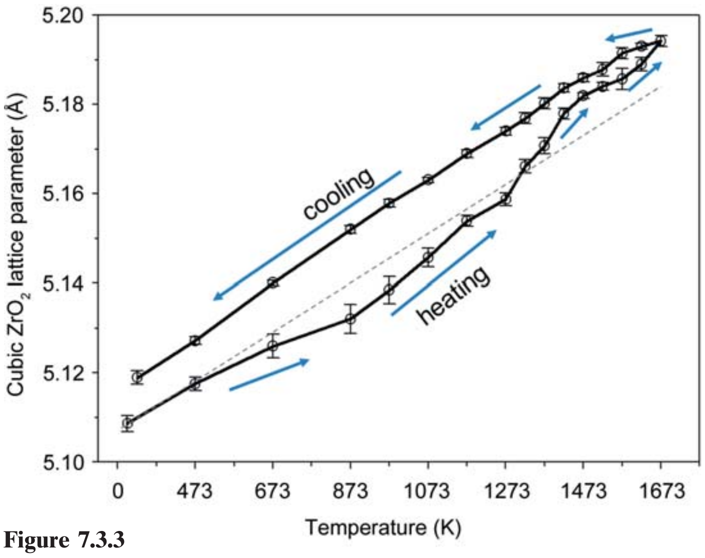

Figure 7.3.3
Lattice-parameter variation for an iron-doped YSZ heated/cooled under inert conditions. Figure reproduced with permission from Coker *et al.* (2012). Copyright (2012) JCPDS – International Centre for Diffraction Data. Reproduced with permission.

approximately 673 K (see Fig. 7.3.3). The dashed line in the figure represents the interpolated linear thermal expansion and serves as a guide to the eye for detecting behaviour that deviates from linearity. Above 673 K, upon heating one observes a drop below the linearity trend line. This observation suggests a subtle increase in iron solubility. It was noted that at this point in the diffraction data, the trace phase of Fe_2O_3 began to dissipate, possibly suggesting migration of the iron into the YSZ. However, upon further heating above 1273 K, one observes a more rapid change in slope, suggesting a *decrease* in iron solubility. At this point, wustite (FeO) was observed to form as a second phase, suggesting iron migration out of the ZrO_2. On cooling, the lattice shows a linear behaviour, suggesting that there is no variation in iron solubility, and inspection of the XRD pattern showed that the second phase of FeO persisted. The final lattice parameter of the cycled YSZ was a = 5.124 (3) Å, showing an increase of +0.014 Å from the initial cell dimension prior to heating. Subsequent reprocessing of the sample in an air environment to ~1773 K (not shown) can regenerate the more iron-soluble form of YSZ, returning it again to the initial state of high iron doping. Our ability to detect and monitor iron shuttling in and out of the ZrO_2 structure with temperature and atmospheric conditions has shed light on the understanding of the conditions within the ZrO_2 during the CO_2 splitting reaction. A point worth mentioning here is the sensitivity of XRD unit-cell parameters. Careful analysis can reveal changes in the unit-cell dimensions of the order of thousandths of ångstroms. As can be seen from Fig. 7.3.3, the error bars for each data point are in the 0.001–0.003 Å range. Hence, significant changes in cell dimensions of 0.005 Å are possible when employing well aligned powder diffraction instrumentation, and even greater precision is possible (down to the ±0.0005 Å range) for meticulous measurements.

7.3.6. Battery technology

There are many applications for XRD in the science of battery-based energy storage. Of particular interest are the chemical reactions, phase changes and morphological/microstructural variations that can occur at the anode and cathode inside the cell. Many of these characteristics can have significant impact on battery life, energy capacity and modes of failure. One example where the use of PXRD is paramount for cell design and fabrication has to do with the cathode of the lead–acid battery. Lead–acid battery technology has been in existence since the late 1800s and has proven to be the most successful rechargeable battery technology in history (Kurzweil, 2010; Lukic *et al.*, 2008). The use of PbO_2 as the cathode material makes sense in terms of economics and with regard to the simplicity of the cell design (where Pb is employed as the anode). The critical nature of the PbO_2 cathode is that it forms as the tetragonal β-PbO_2 phase, rather than the orthorhombic α-PbO_2 compound (Abaci *et al.*, 2000). This is because the α-PbO_2 phase displays a much lower electrical conductivity than the β-PbO_2 (almost an order of magnitude), as outlined by Mindt (1969). The synthesis procedure employed for generation of the PbO_2 cathode can have a major effect on which polymorph is formed, and detection and quantification of the α *versus* β phase fraction is straightforward from standard PXRD measurements (Abaci *et al.*, 2000). Such a clear tie between structure, property and performance allows for a means of process-quality control through a mechanistic understanding of battery function, all with a simple application of PXRD.

Li-ion battery technology benefits significantly from PXRD in a similar manner to other materials-science systems. The cathode tends to be the capacity-limiting factor in Li-ion cells, and therefore new compounds are under continual development. For example, Pouillerie *et al.* (2001) analysed various Mg-doped cathode compounds based on the $LiCoO_2$ layered structure. XRD analysis was performed in a 'post-mortem' fashion where batteries were first constructed with various cathode compounds, cycled (*i.e.* charged and discharged) and then disassembled for XRD analysis of the cathode material. This is a straightforward but time-consuming process. However, it is possible to obtain a great deal of information through this method. Pouillerie *et al.* (2001) have reported the impact of cycling on the performance of the battery by looking at the structural parameters of layered-$LiCoO_2$-type cathode compounds after just one cycle, and likewise after 500 cycles. Structural parameters such as lattice parameters, atom positions, site occupancies, crystallite size and microstrain can be derived from Rietveld structure refinement. Based on these results, it was determined that a small amount of Mg doping of these cathode materials reduced the fade (loss of capacity with cycling). Again, understanding of the Mg-site location, as determined by structure refinement, yielded the necessary mechanistic insight concerning the observation of improved performance. Pouillerie *et al.* (2001) found that Mg migrated from the Li site to the inter-slab site during cycling. The irreversible Mg migration aided the stability of the structure and reduced delamination of the cathode phase. These types of analyses prove much more informative than iterative trial-and-error processing. They illustrate the fundamental difference between the often slow, incremental improvement obtained by empirical approaches to the more mechanistic understanding of structure/property/performance relationships made possible in part through materials characterization.

One drawback of the 'post-mortem' technique is that one must assume that the disassembled material (such as cathode powder from a disassembled cell) represents what is present within the cell at the given state of charge (SOC). Electrochemical cells can display complex chemical reactions and in a sealed environment may form compounds that are unstable in air. Thus, disassembly of the battery and exposure to the environment may result in analysis of reaction products caused by air exposure. This is likely to prove confusing and even misleading in terms of the results and ultimate conclusions drawn from the analysis. Methods have been developed for the 'post-mortem' analysis of materials that display air sensitivity (see Rodriguez *et al.*, 2008). However, if one truly desires to obtain information regarding the chemical changes occurring within a battery, it would seem best to monitor these reactions *in situ* while simultaneously collecting the electrochemical cell response. Such *in situ* analyses have been performed (see Reimers & Dahn, 1992) and can yield much greater insight into battery performance because the structural data obtained *via* PXRD can be directly tagged to a simultaneous property measurement (*i.e.* SOC) and the results from each diffraction pattern can be viewed in context; that is, in comparison to the pattern before and the pattern after. The contextual aspect of the data set can be important for identification of experimental artifacts, and enables detection of trends in data while yielding the additional facet of property comparison. Fig. 7.3.4 shows such an *in situ* diffraction data set collected on the compound $Li_8Ni_5Co_2MnO_{16}$ (Boyle *et al.*, 1999). The figure shows the resulting PXRD patterns collected on this cathode material while the sample was charged, thus pulling Li out of the cathode material. The electrochemical cell was fabricated using poly-

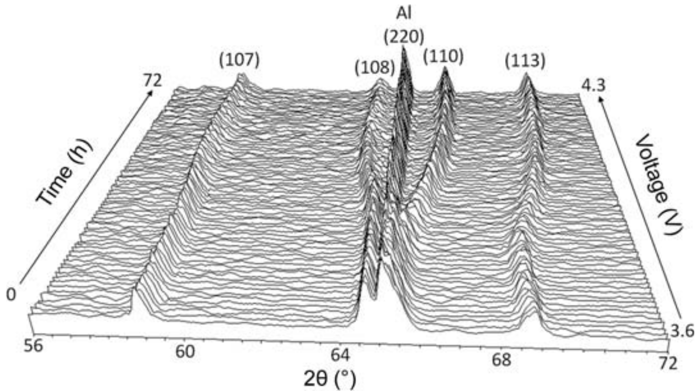

Figure 7.3.4
In situ XRD analysis of $Li_8Ni_5Co_2MnO_{16}$ during charging. The distortion of the unit cell during Li removal (charging) is manifest by shifting of peak positions in 2θ. The Al (220) peak is from the current collector and can serve as an internal standard. (Data source: internal Sandia research, unpublished.)

propylene plastic (see Rodriguez *et al.*, 1998). This ‘coffee bag’-type cell could be directly incorporated within the diffractometer. The results show peak-position shifts during charging. Only a limited 2θ range is shown in Fig. 7.3.4 because superpositions of other diffraction signals associated with different aspects of the cell (*i.e.* plastic, Li metal, separator *etc.*) can make analysis of the entire diffraction pattern difficult. The particular 2θ range shown here (56–72° 2θ) is useful because it is primarily composed of diffraction from the cathode, which is of interest in this experiment (Rodriguez *et al.*, 2000). As the cell is charged, the Li^+ ions are shuttled from the cathode to the anode (lithium metal). As the Li^+ ions are removed from the $Li_8Ni_5Co_2MnO_{16}$ cathode, the unit cell of this rhombohedral/hexagonal ($R\overline{3}m$) phase shows different behaviour for the *a* and *c* axes. The Miller indices for the individual peaks are labelled in the figure. The (107) and (108) peaks are particularly sensitive to the *c*-axis changes, while the (110) peak is strictly dependent on changes associated with the *a* axis. This is convenient because it allows for detection of changes in both axes for this structure. The (113) peak is affected by both *a* and *c* axes and perhaps serves as a good indication of the overall volume change in the cell. Lattice-parameter refinements of the initial unit cell (*i.e.* 0% SOC) indicate $a = 2.85$, $c = 14.19$ Å, $V = 99.80$ Å^3 and the final lattice parameters at 100% SOC (4.3 V) are $a = 2.80$, $c = 14.46$ Å, $V = 98.20$ Å^3. The implications of these results are that upon Li^+ removal, the *c* axis of the cathode material expands while the *a* axis shrinks, resulting in a net reduction in the unit-cell volume for the cathode material. This cell distortion is anisotropic at the scale of the individual crystallites. Note also that there is an aluminium (220) peak present throughout the entire pattern series. The Al is from the current collector and its presence is problematic due to overlap with the (110) peak profile. However, the Al (220) peak only overlaps the (110) peak from the cathode at the early stages of charging and the two peaks separate more as the sample reaches significant SOC voltages. Profile fitting easily deals with this overlap condition. As it turns out, the presence of the Al (220) peak can be helpful because it can be employed as an internal standard. This is because the *d*-spacing for the Al (220) peak should be unaffected by the charging process. As one can see in Fig. 7.3.4, the Al (220) peaks remain static in 2θ during the charging sequence. Methods for dealing with the convolution of *in situ* measurements have been addressed through the use of multivariate statistical analysis (MSA), which allows for the separation of large data sets into individual components, thereby reducing the complexity of the data set and separating reaction behaviour from the signal associated with static (inert) portions of the data set (Rodriguez *et al.*, 2007, 2010). This has proven to be a powerful technique for isolation of the dynamic behaviour within the *in situ* data collection.

A thermal battery is an electrochemical cell whose electrolyte takes the form of a solid-state salt (*e.g.* LiCl or KCl). The cell is fabricated with an anode, a cathode and a separator medium, and the salt electrolyte remains solid and inactive until the entire pile is heated. Upon heating, the electrolyte melts and the cell can be utilized as a power supply. These batteries are very useful when there is a need for an autonomous power supply with a long shelf-life that can be called upon at a moment’s notice to generate electrical power. PXRD can be employed in the analysis of these cells for phase identification of initial battery configurations as well as in cells that have undergone discharge (Wesolowski *et al.*, 2011; Griego *et al.*, 2012). Microdiffraction (μ-PXRD) has been performed on thermal battery cross sections to diagnose the phases present before and after cell discharge. The benefit of μ-PXRD (*e.g.* ∼500 μm spot size X-ray beam) is that diffraction data can be obtained spatially, thus giving an assessment of the phases present at reaction interfaces such as those which occur in battery stacks. Typically, thermal batteries are composed of layers of anode/separator/cathode; the electrochemical reaction front will begin at the anode/separator interface, and likewise at the cathode/separator interface, and progress outward toward the terminating outer surface of the anode or cathode. To monitor the electrochemical reaction, cells can be heated and then subsequently quenched at various locations on an SOC curve. Then cross sections of the battery stack can be made (*via* standard metrology preparation methods) and one can employ μ-PXRD measurements stepwise across the interface to study the phase changes. Fig. 7.3.5 is such a cross-sectional analysis using μ-PXRD. This specimen was a cell that was near full discharge. The figure shows 2θ on the *x* axis, scan number on the *y* axis (equivalent to the sample translation step) and intensity is shown as a colour contour (purple = low counts, red = high counts). The coloured lines running vertically indicate diffraction peaks. An optical image of the cross section is shown on the right of the μ-PXRD contour plot. Previous analysis on an unreacted sample (not shown) revealed that the anode material started as $Li_{13}Si_4$, the cathode was CoS_2 and the separator was MgO. Salts composed of Li and K cations with Cl and/or Br anions served as the electrolyte. As one can see from Fig. 7.3.5, the anode now contains the $Li_{12}Si_7$ phase, suggesting considerable loss of Li. Likewise, the cathode phase has changed to Co_9S_8, indicating loss of sulfur. There is a significant reaction product of Li_2S throughout the cathode and across a portion of the anode. It appears that there are two distinct regions in the reacted anode. One region, closer to the anode/separator interface, shows Li_2S along with Li_4SiO_4 and a relative deficiency of the $Li_{12}Si_7$ phase. The second region in the anode is further away from the anode/separator interface and is highlighted by the abrupt termination of the Li_2S phase. The region nearer the anode/separator interface may possibly be contaminated by oxygen, forming Li_4SiO_4. The MgO separator typically remains inert during discharge due to its unlikely chemical reduction. It seems more plausible that there was another source of oxygen present. It is also notable that the optical image, shown on the right side of the contour plot, shows cracks and fissures across the separator. Typically these cells are discharged under inert conditions. The observation of Li_4SiO_4 at the anode/separator interface may be consistent with loss of such inert conditions during discharge. It is worth

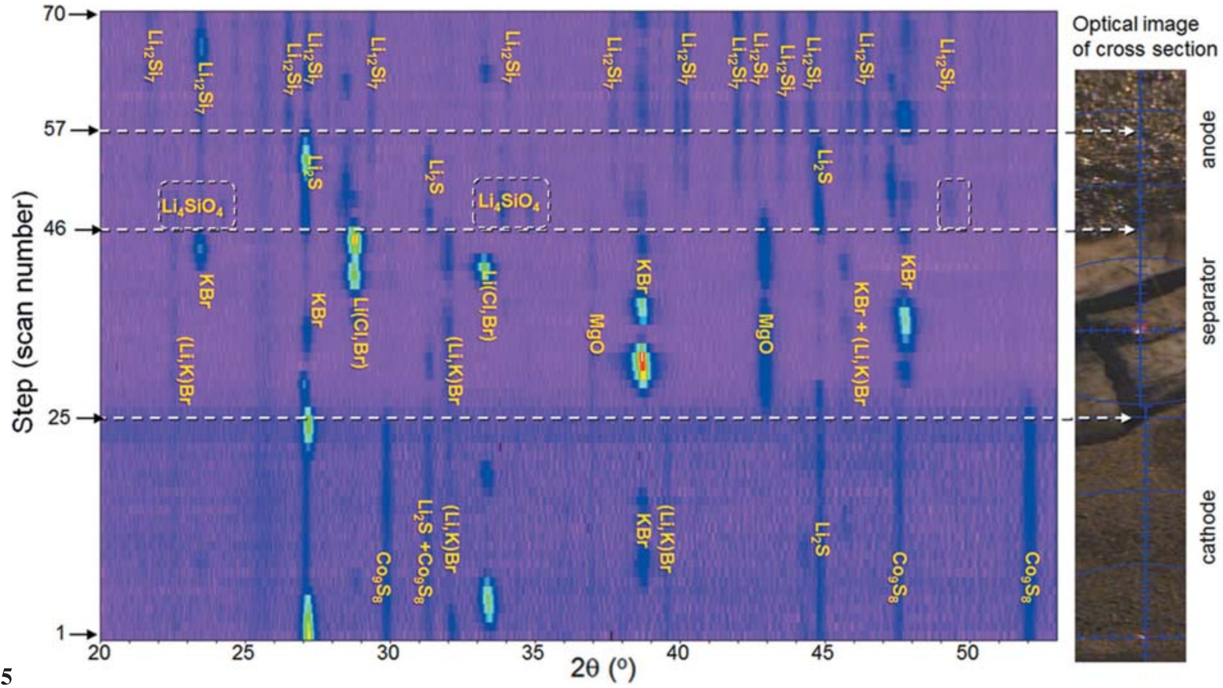

Figure 7.3.5

Contour plot showing spatial dependence of phases across a processed thermal battery. Regions separated by horizontal dotted lines indicate boundary interfaces between anode/separator/cathode sections. An optical image of the sample cross section is shown to the right of the contour plot. (Data source: internal Sandia research, unpublished.)

commenting about the discontinuous peak intensities for the alkali halide salts as one moves from cathode to separator to anode regions. For example, the KBr (220) peak at ~38.5° 2θ shows discrete intensity spikes at various steps across the contour map. This is an artifact of large grain size *versus* small beam size. As the X-ray beam becomes smaller, the fraction of illuminated crystallites is reduced as well. The small spot size impacts the statistical distribution of grain-orientation sampling as the diffraction experiment begins to approach a single-crystal condition. These data were collected with the use of an area detector, which improves sampling statistics by collecting more of the solid angle of the Debye cone. However, the electrolyte often contains large crystallites (> 100 µm) which, when encountered during the sequential step analysis of the small X-ray beam, would comprise a disproportionate fraction of the diffracted volume and lead to these spikes of intensity. The benefit of a spatially dependent analysis allows for easy diagnosis of this effect through visual inspection of the contour plot, and enables improved phase identification through merging of scans taken across different parts of the cross section so as to obtain a single, representative 2θ scan for each region (*e.g.* separator section). From this example, one can see the benefits of µ-PXRD for diagnostics and failure analysis for thermal-battery energy-storage devices.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the US Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000. The author would like to thank James Griego for his aid in formatting aspects of this manuscript.

7.4. Powder diffraction in art and archaeology

G. Artioli

7.4.1. Introduction

The cultural heritage of mankind includes virtually all materials that humans have employed in their activities during prehistory and history, from the early use of natural organic and mineral compounds as tools for everyday survival to the modern sophisticated and highly symbolic use of technological-age materials in contemporary art. The materials pertaining to cultural heritage therefore potentially encompass most known compounds and their combinations, thus requiring the most advanced and powerful analytical and characterization tools. General targets are: (1) to define the nature and role of the materiality of the objects in relation to human activities, that is the past processes of manufacturing, transformation and use (Tite, 2001); (2) to reconstruct the original state of the materials and recognize the active and past degradation and alteration processes for conservation purposes (May & Jones, 2006); and (3) to establish the physical basis for appropriate interpretation of the intangible part of the cultural heritage (Bouchenaki, 2004).

Cultural-heritage investigations are broadly covered by archaeological science (or archaeometry) and conservation science. *Archaeometry*, a term largely used to describe the quantitative characterization of archaeological objects and processes (Tite, 1991), mainly deals with point (1) above, attempting to relate the materials to the associated past human activities. *Conservation science*, mostly related to curatorship, art history, museum conservation and restoration of art works, mainly deals with point (2) above; the main focus is preservation of heritage for future generations. In terms of the scientific techniques employed in the practical investigations of materials and the methodologies adopted, the two disciplines overlap considerably. Both sciences attempt to interpret cultural-heritage materials and objects (whether related to archaeology or art) as inserted into a timeline related to human activities, that is to understand the evolution of the materials from the raw natural sources, through the man-made production and transformation processes (often involving pyrotechnology), and their use, diffusion and consumption until their disposal, degradation or perhaps their conservation in cultural collections (Fig. 7.4.1). In short, science as applied to cultural-heritage studies is bound to define the present status of the material and the thermodynamics and kinetics of the processes acting on it in order to retrieve information on its past, and to optimize the methods for its preservation for future generations (Artioli, 2010*b*).

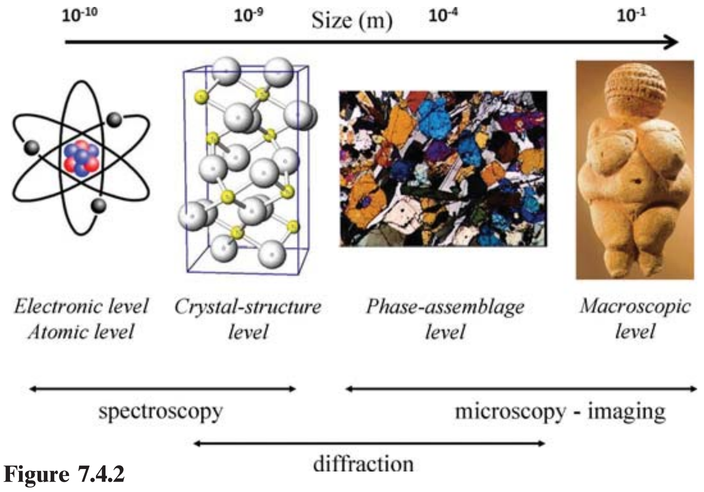

Figure 7.4.2
Different levels and scale of investigation of cultural-heritage materials. Diffraction is most suited to providing information at the crystal-phase level.

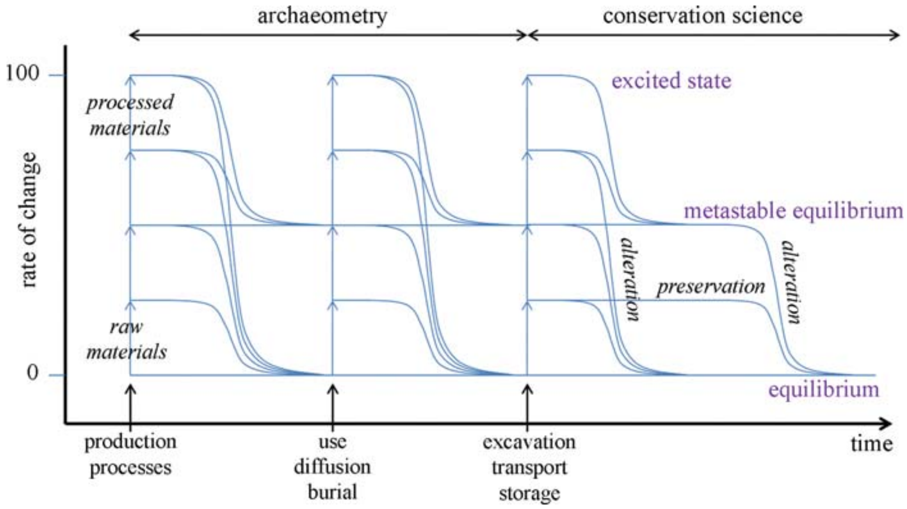

Figure 7.4.1
Rates of change in time for cultural-heritage objects and materials. Rapid changes may occur (*a*) at the manufacturing time of the object, when raw materials are processed and transformed into final objects, often by high-temperature processes, (*b*) during its lifetime (use, diffusion, change of environment and burial) and finally (*c*) during excavation and insertion into collections. Between these events, alteration tends to bring the object back to equilibrium with the environment, whereas conservation processes generally tend to preserve the object in the last metastable state reached during lifetime or burial (modified from Artioli & Angelini, 2011).

All scientific disciplines and available characterization techniques may to some extent contribute to cultural-heritage studies. However, diffraction proves to be invaluable because of its intrinsic sensitivity to crystalline solids. Provided that cultural-heritage materials may be probed at different levels and scales (Fig. 7.4.2), at a first approximation we may state that diffraction is the most important technique for probing materials at the 10^{-9}–10^{-3} m level, yielding information on the crystal phases and their structural arrangements at the atomic and molecular level, besides helping to define the size, shape and orientation of the crystallites. Each of these types of information is discussed in detail.

7.4.2. The information provided by diffraction

X-ray diffraction is the only routine technique in solid-state research that is intrinsically

Table 7.4.1
Mean penetration depth of different types of electromagnetic radiation or particle beams into common materials.

Material (density in g cm^{-3})	Soft X-rays (1 keV)	Cu $K\alpha$ (8 keV)	Hard X-rays (30 keV)	Thermal neutrons (25.3 meV)	Protons (2 MeV)	Electrons (30 keV)
Fe (7.87)	0.1 µm	4.2 µm	0.2 mm	8.3 mm	19.2 µm	2.1 µm
Quartz (2.64)	1.2 µm	0.1 mm	4.8 mm	3.5 cm	39.2 µm	6.2 µm
Bone (1.80)	1.3 µm	0.1 mm	4.9 mm	2.8 cm	46.5 µm	9.1 µm
Polypropylene (0.90)	5.9 µm	2.9 mm	4.7 cm	1.5 mm	74.6 µm	18.3 µm
Wood (0.59)	5.2 µm	2.0 mm	6.1 cm	5.2 cm	144.7 µm	27.9 µm

sensitive to the long-range order and symmetry in crystals. For 100 years since von Laue's discovery of the interaction between X-rays and crystals, it has allowed the analysis of crystal structures at the atomic and molecular level, providing the means of characterizing and interpreting the intimate nature of crystalline compounds from simple elemental and ionic solids to complex macromolecules. Because of the methodological advances and the versatility of present-day instrumentation, X-ray, neutron and electron-diffraction techniques are considered among the established basic tools for the analysis of materials. Traditionally, X-ray powder diffraction has been the technique of choice for the rapid and efficient identification of polycrystalline compounds, whereas single-crystal diffraction was and is the preferred technique for structure solution and analysis, although the recent advances in whole-pattern profile analysis (Dinnebier & Billinge, 2008) have considerably expanded the potential and applicability of powder diffraction. The power of powder diffraction, combined with the fact that the vast majority of archaeological and art materials are polycrystalline in nature, mean that powder techniques are universally employed in the field.

Diffraction techniques (Giacovazzo, 2011) in essence provide very basic information on the nature of the material, on its physical state, and on its atomic and chemical arrangement. This information includes: (1) the *phase identification and quantification* of crystalline compounds and complex polyphasic mixtures, (2) the *texture* and *orientation* of the crystalline phases, (3) the *atomic and molecular structure* of the phases involved, and (4) the physical *microstructural state* of the material in terms of crystallite size and accumulated strain. Fig. 7.4.3 schematically summarizes each one of the pieces of information that may profitably be used in cultural-heritage investigations. They will be discussed separately with reference to specific examples.

7.4.3. Phase identification and quantification

Whether we deal with pigments, archaeological ceramics, metals or stone tools, the first steps to understanding the nature of the compounds and the problems involved are invariably (1) a definition of the chemical system by elemental and chemical analysis and (2) the correct identification of the organic and inorganic crystalline phases present in the material by powder diffraction. When dealing with simple minerals or synthetic chemical precipitates, the identification of the crystalline phases is mostly a straightforward procedure, requiring good-quality diffraction measurements (most commonly X-ray powder-diffraction data) and appropriate search–match procedures within reference databases (ICDD Powder Diffraction File: http://www.icdd.com; ICSD – Inorganic Crystal Structure Database: http://www.fiz-karlsruhe.de/icsd.html; CSD – Cambridge Structural Database: http://www.ccdc.cam.ac.uk/Solutions/CSDSystem/Pages/CSD.aspx) (Bish & Post, 1989; Monaco & Artioli, 2011). However, cultural-heritage material can be varied (natural minerals, synthetic products, processed and treated materials, alteration and corrosion products, *etc.*) and potentially very complex. They are frequently polyphasic composites, and depending on the time that has elapsed between their production and their use, their original nature can be severely contaminated, degraded and altered. Phase identification therefore may be a very complicated process, requiring optimized measuring techniques and substantial experience for data interpretation.

From the experimental point of view, the most limiting factors for diffraction studies of cultural-heritage materials are the scarcity of available sample (if the object can be directly sampled) or the surface alteration and the treatment layers covering the original material (if the object cannot be sampled). Modern diffractometric techniques often allow direct non-invasive measurement of the object itself, although the depth of probing is closely related to the measuring conditions (energy of the probe, diffraction geometry *etc.*) and the nature of the material. Laboratory X-rays of course mostly probe just the surface layers of most materials, and bulk measurements must be performed with very energetic synchrotron hard X-rays or neutrons. Table 7.4.1 provides an indication of the mean penetration depth of different electromagnetic radiation or particle beams into matter. The selected diffraction geometry also has important consequences on the probed volume: surface layers (preservation treatments, protecting varnishes, corrosion layers, painting layers, glazes *etc.*) are conveniently explored with X-rays under glancing-angle conditions or through synchrotron microbeams (see, for example, the analysis of varnishes of ancient musical instruments: Echard & Lavédrine, 2008; Echard *et al.*, 2008); bulk analysis of the internal part of the objects is of course better performed using hard X-rays or neutrons (Kockelmann *et al.*, 2006). The powder-diffraction analysis of ancient Egyptian cosmetics contained in well-preserved sealed vessels (Martinetto

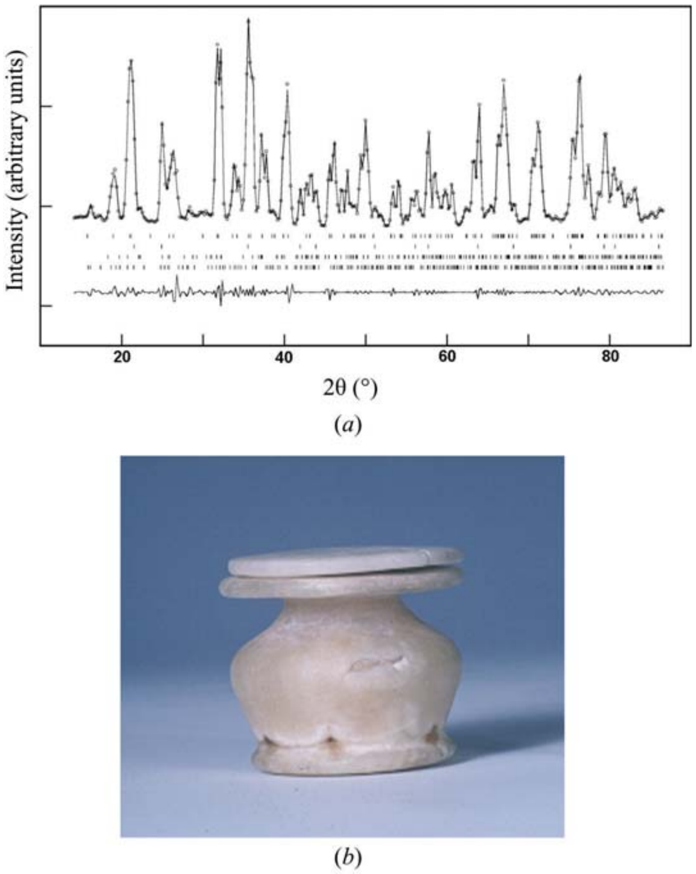

Figure 7.4.4
A neutron powder diffraction profile (*a*) of ancient Egyptian cosmetics contained inside a sealed vessel (*b*). Penetrating neutron beams allow phase identification of the material in a totally non-invasive mode (from Martinetto *et al.*, 2003).

et al., 2003) is a good example of phase identification through thick objects thanks to non-invasive penetrating neutron beams (Fig. 7.4.4).

One important aspect to be considered when working with extremely small quantities of powdered material or with microbeams that probe very small volumes of sample in a non-invasive way is the incomplete powder averaging of the diffraction signal, since the sample is far from an ideal polycrystalline sample having a large number of randomly oriented crystallites. In such cases, and also when using portable X-ray diffraction (XRD) probes, much caution should be taken in interpreting the data. If possible, repeated measurements through different directions in the sample should be performed when using point or linear detectors, and as much reciprocal space as accessible should be analysed when using two-dimensional detectors.

Besides phase identification, modern powder diffraction is a very powerful tool for the quantification of crystal phases in polyphasic mixtures (Madsen & Scarlett, 2008). Quantitative analysis applied to cultural-heritage materials is commonly used to characterize the phases relative to specific production processes, to trace the provenance of materials, to understand the details of the manufacturing techniques or to evaluate the degradation state of the object. If the phase quantification is carried out in great detail, the results may be used as a powerful discriminatory tool to distinguish apparently similar materials such as ancient mortars produced with slightly different raw materials and/or in different times (see, for example, Secco *et al.*, 2010; Artioli, 2010*a*). The statistical discriminant analysis performed on the phase quantities is analogous to that performed on chemical or isotopic tracers.

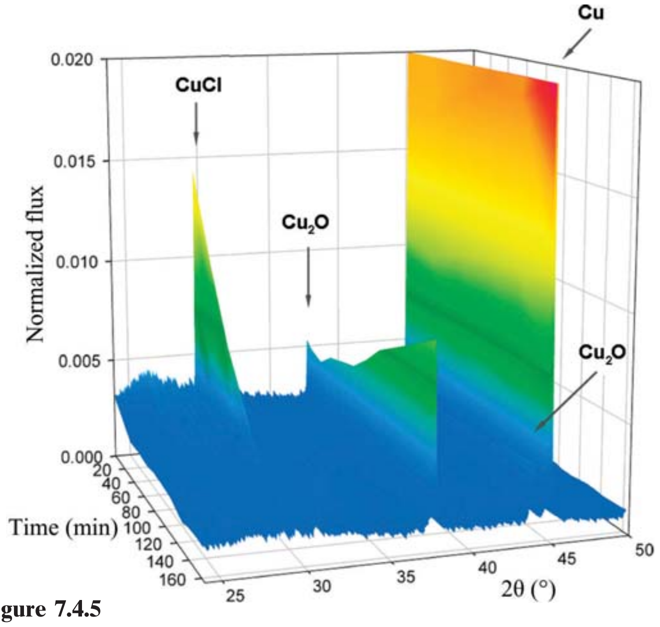

Figure 7.4.5
Synchrotron-based techniques have been used to evaluate corrosion-potential measurements as monitoring method for copper-based objects recovered from marine environments (from Adriaens & Dowsett, 2010). The extraction of chlorides from the corroded metal artifacts is required for conservation, since their presence will restart the corrosion process in very short times.

One interesting application is the *in situ* quantification of crystalline phases during the artificial treatment of the sample, for example under confined chemical conditions or at non-ambient pressure and temperature. Such *in situ* diffraction techniques require special sample-conditioning chambers and optimized experimental setups. These experiments yield crucial information on the kinetics of the processes, for example the determination of the rates of the corrosion processes in archaeological metals that are crucial for conservation purposes (Leyssens *et al.*, 2005). More specifically, synchrotron-based techniques have been employed to evaluate the use of corrosion-potential measurements as a visible monitoring method for copper-based objects recovered from marine environments (Fig. 7.4.5: Adriaens & Dowsett, 2008, 2010). High-temperature diffraction is also a very useful technique for assessing the phase transformations taking place during pyrotechnological processing. It has been successfully used to investigate cinnabar decomposition and the precipitation of silver particles in the lustre layer of medieval glazed ceramics (Pradell *et al.*, 2008), and in principle it could be used to assess directly the firing conditions of archaeological ceramics, for example by measuring *in situ* the reactivation temperature of the phase transformation. However, to date X-ray powder diffraction is mostly used at ambient conditions to check the products obtained by high-temperature firing of clays (Häusler, 2004).

7.4.4. Crystal structure analysis

Detailed knowledge of the crystal structure of heritage materials at the atomic or molecular levels is rarely required in routine investigations. However, for particular materials the atomic arrangement may provide the key to understanding the physicochemical properties and the reactivity of the phase. Pigment phases in paintings and frescoes are pertinent examples of important heritage materials that frequently require very detailed investigations to pinpoint the nature of the colouring mechanisms, the conservation state and their predicted variation in time. Advanced laboratory and synchrotron-based diffraction techniques are increasingly used in combination with complementary spectroscopic ones (especially X-ray absorption spectroscopy) in order to identify the pigments and their distribution in paint layers (see, for example, Welcomme *et al.*, 2007; Herrera *et al.*, 2008; Duran *et al.*, 2010), thus accessing information about the sub-surface layers and the pigment micro-spatial distribution (Cotte *et al.*, 2007, 2010). However, in complex cases the definition of the pigment and the complete understanding of its physico-chemical behaviour require knowledge of the atomic structure [see, for example, the case of Naples yellow (= lead antimonate); Dik *et al.*, 2005], and this can be a challenging task. Two classic examples involving rather complex crystal structures are the Maya blue and the Catalan blue pigments (Fig. 7.4.6).

Maya blue is the unusually stable typical blue colour present in Mayan frescoes and objects (Reyes-Valerio, 1993). Despite a large number of investigations, it has escaped full characterization for more than 50 years (Gettens, 1962), although it has long been recognized that it is a combination of an inorganic compound, the mineral palygorskite, and an organic part, the indigo molecule extracted from *Indigo sp.* plants. Ongoing investigations aimed at achieving a satisfactory model of the hybrid organo-clay complex include high-resolution transmission electron microscopy, proton-induced X-ray emission, X-ray absorption spectroscopy, Raman spectroscopy, thermal analysis and molecular modelling, beside a substantial number of structural studies (for a complete account, see Sanchez del Rio *et al.*, 2011, and references therein). Recent structure analysis by synchrotron X-ray and neutron diffraction clarified that the indigo molecule is indeed absorbed inside the zeolitic channels of the palygorskite clay, and that there is strong interaction between the organic molecule and the hosting framework. However, it is known that the palygorskite mineral system is invariably composed of at least two polymorphs, one orthorhombic and one monoclinic, that the structure may have extensive polysomatic defects (the palysepiole polysomatic series; Ferraris *et al.*, 2004), and therefore sepiolite impurities are frequently present. The real system is therefore substantially more complicated that the assumed models, and further work is required to sort the details of the pigment actually used in Mesoamerica.

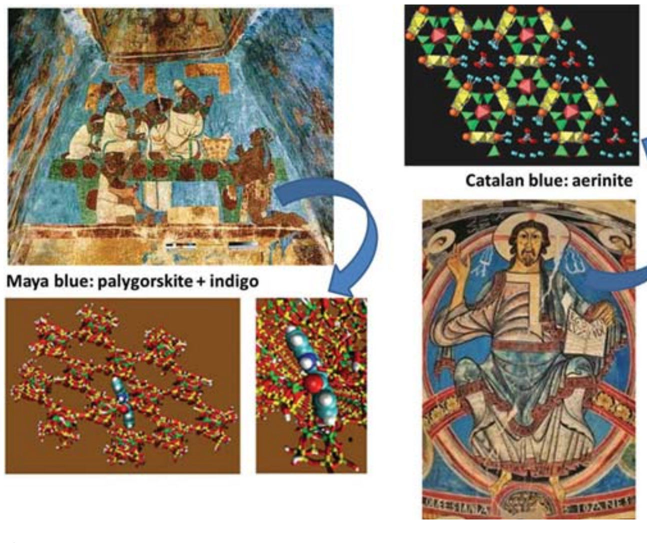

Figure 7.4.6
The crystal structure analysis of Maya blue (palygorskite) and Catalan blue pigments (aerinite) proved to be challenging tasks, both achieved through powder-diffraction analysis. Knowledge of the structural arrangements is fundamental in understanding their physico-chemical behaviour and pigmenting properties.

Catalan blue is also a very stable pigment, used in most Catalan Romanesque paintings between the 11th and 15th centuries. It has long been known to be essentially composed of the mineral aerinite, although its complex pyroxene-related structure remained unsolved until very recently (Rius *et al.*, 2004, 2009). In the aerinite case, synchrotron-radiation diffraction was pivotal not only in allowing the structure solution and subsequent refinement of the mineral, but also in determining the painting-layer stratigraphy with high spatial resolution of several church frescoes from the central Pyrenees, thus confirming the presence of aerinite-based pigments and therefore close artistic connections between Occitanian churches in the Pyrenees and the Catalan Romanesque paintings (Salvadó *et al.*, 2008).

7.4.5. Texture analysis

The inhomogeneous spatial distribution of crystallites in a sample implies an inhomogeneous distribution of Bragg intensity in the Debye rings. The measurement of the variation in intensity along the diffraction rings allows calculation of the so-called orientation distribution function (ODF) of the crystallites, that is, the function that statistically describes the crystallographic orientation of the crystals in the samples with respect to the sample orientation (Kocks *et al.*, 1998; Popa, 2008). Orientation distributions are generally represented graphically by means of pole figures in direct (*i.e.* the sample space) or inverse (*i.e.* the crystallographic space) space (Monaco & Artioli, 2011).

Since the shape and orientation of the crystallites in a solid depend on its thermo-mechanical history, the measurement of the crystallographic textural features of the sample (crystallographic texture analysis: CTA) is a powerful tool for determining the manufacturing process of an object: its application is especially important for archaeological and historical metals. The main technique universally used to interpret heritage metals is metallography (Scott, 1991), invasively performed by reflected-light optical microscopy on small polished and etched sections of the object's surface. CTA based on diffraction data has been proposed as a totally non-invasive alternative technique to conventional optical metallography (Artioli, 2007, 2010*b*, pp. 343–348). It should be noted that for metals and averagely absorbing materials, texture analysis performed with X-rays gives only a description of the surface layer of the sample, whereas the same analysis performed with deeply penetrating neutrons may yield a more appropriate interpretation of the bulk. Fig. 7.4.7 shows an example of the pole figures resulting from the full CTA analysis of a prehistoric copper axe; the data allow complete interpretation of the metallurgical processes employed to produce the object (Artioli *et al.*, 2003).

7.4.6. Microstructural analysis

A careful analysis of the profile shape of the diffraction maxima of a polycrystalline material and of their angular dependence can give information on the size distribution of the crystallites and on the presence of lattice strains. This is commonly referred to as microstructural analysis of the sample, and it describes the measured profile as the convolution of the sample-dependent effects with the instrumental contributions (Snyder *et al.*, 2000). Strain measurements, which are particularly important in the evaluation of residual stress present in industrial materials and engineering components, may also be profitably used to characterize cultural-heritage materials.

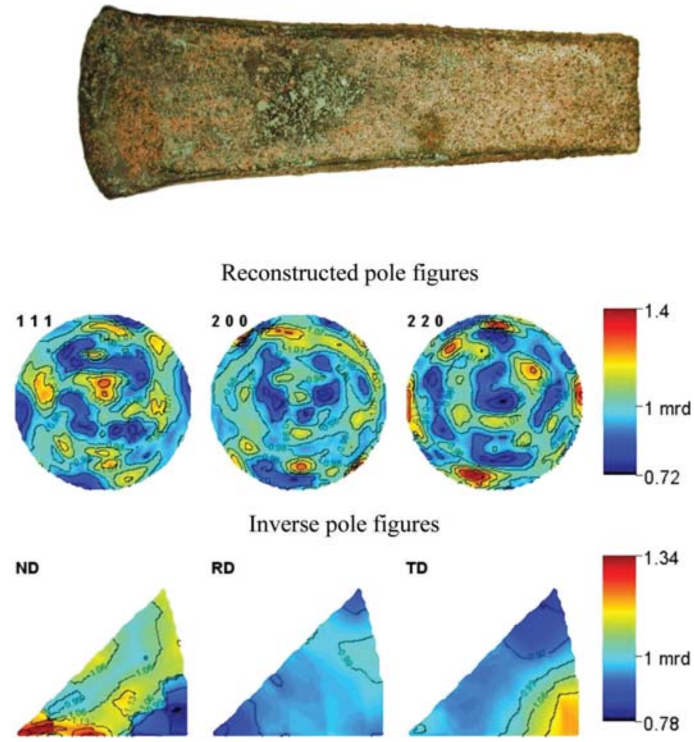

Figure 7.4.7
Recalculated and inverse pole figures for the Remedello copper axe from Tomb 102 (Artioli, 2007). The main recognizable features are weak 310 and 110 components of the fibre texture caused by mechanical working and the strong $\{100\}\langle 100\rangle$ cube recrystallization texture due to substantial thermal annealing.

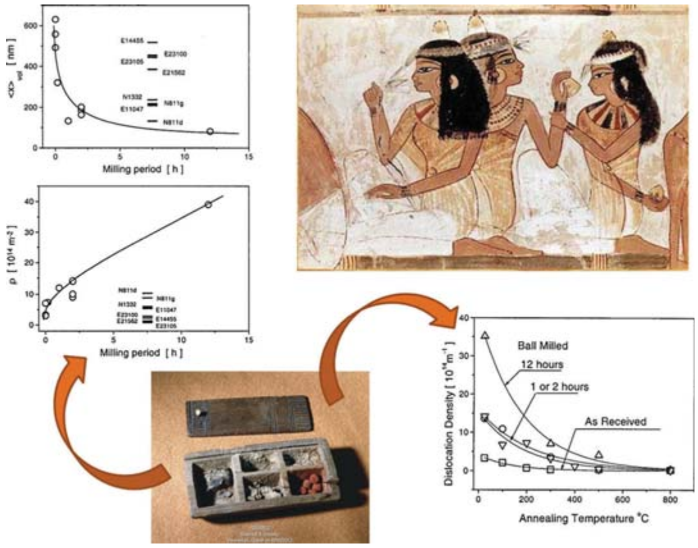

Figure 7.4.8
Detailed microstructural analysis of high-resolution synchrotron powder data of galena as the main ingredient in ancient Egyptian kohl (Ungar *et al.*, 2002, 2003). The archaeological samples are compatible with a controlled process that included grinding and thermal annealing, as inferred from the measured mean size and dislocation density in the crystallites of standard samples of galena prepared under controlled conditions. Reproduced with permission from Unger *et al.* (2002). Copyright (2002) AIP Publishing LLC.

The most illustrative example of microstructural analysis from the diffraction-peak broadening of heritage materials is the careful investigation of ancient Egyptian cosmetics performed by the joint Louvre–ESRF–CRNS group (Walter *et al.*, 1999; Tsoucaris *et al.*, 2001). In-depth analytical work performed by high-resolution synchrotron X-ray diffraction showed unequivocally that the large grain size and the significant particle strain of Egyptian kohl are related to hand grinding of galena particles (Fig. 7.4.8), whereas the small crystal size and lack of strain of Egyptian white pigments (mainly laurionite, hydrocerussite) are compatible with chemical precipitation (Martinetto *et al.* 2000, 2001; Ungar *et al.*, 2002, 2003). The careful control of the grinding and thermal annealing treatments of black galena, together with mixing with different proportions of white cerussite, allowed preparation of make-ups with specific colour shades and adhering properties. This neatly confirmed that the science and business of cosmetics started a long time ago (Martinetto *et al.*, 1999).

7.4.7. Present trends

It is appropriate to complete this brief overview with a few comments on present trends in the use of diffraction instrumentation and techniques applied to cultural-heritage materials.

(1) There is a general trend to produce and make use of portable instrumentation, either portable X-ray powder diffractometers or combined instruments performing diffraction and X-ray fluorescence analysis. A number of prototypes and a few commercial instruments are available on the market, the most successful ones applying instrumental technology similar to that selected for the Mars Science Laboratory (MSL Chemin Instrument: Yen *et al.*, 2012). This 'labs go to the museum' attitude (Artioli, 2010*b*) is equally welcomed by the manufacturers in search of novel markets and by cultural-heritage workers (museum curators, archaeologists, conservators *etc*.) who would like fast-access analyses in the most diverse situations: archaeological excavations, field surveys, wide screening of museum objects, outdoor architecture, monument characterization and the like. Although the trend is certainly positive, since it allows characterization of objects that cannot be taken to diffraction laboratories or sampled (for example statues, frescoes *etc.*), it should be stressed that the data obtained in non-standard laboratory conditions are frequently biased, especially for quantification purposes. Therefore the results from portable instrumentation are acceptable only as long as the approximate quality of most of the data obtained is recognized and the data are used accordingly. The danger is that low-quality, misleading or even wrong data may proliferate and be hard to contest should they enter the literature.

(2) In parallel to the fast development of laboratory diffraction instrumentation, large-scale facilities, especially synchrotron X-ray sources and neutron beams, are increasingly becoming available. In most cases access is provided by national and international institutions, so that their use is likely to expand among research groups.

Synchrotron facilities are being optimized for *microbeams* (Janssens & Van Grieken, 2004; Creagh, 2007; Bertrand *et al.*, 2012) and for simultaneous or combined two- and three-dimensional mapping of fluorescence, absorption and diffraction signals. The spatial correlation of the diffraction and spectroscopic signals is crucial in order to disentangle the presence of different compounds in complex polyphasic mixtures. These multi-spectral techniques yield complementary space-resolved information on chemical speciation and phase composition: they represent powerful tools for the characterization of cultural-heritage materials at the micron or sub-micron scale (Fig. 7.4.9), including for example metals (Friedman *et al.*, 2008; Young *et al.*,

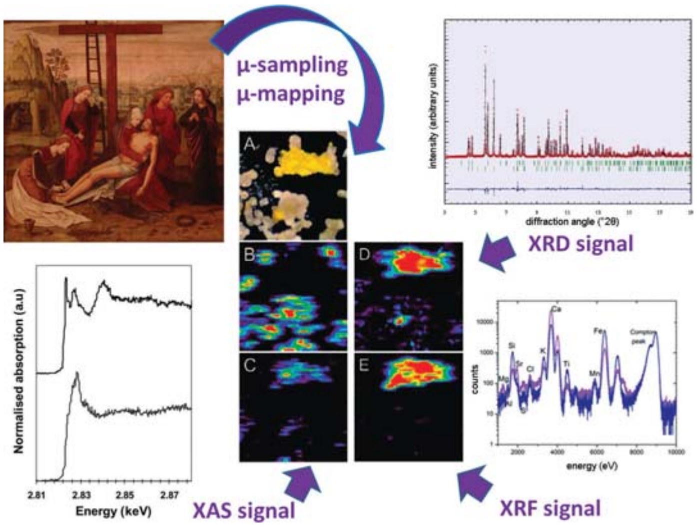

Figure 7.4.9
Schematic diagram showing the potential of simultaneous two-dimensional micro-mapping using synchrotron radiation to excite multiple signals. Combined interpretation of the maps allow extraction of information concerning the crystal phases from XRD, elemental chemistry from X-ray fluorescence and oxidation state of selected elements from X-ray absorption spectroscopy. (The scheme is not related to a single experiment, but rather a collage of pictures and data from various sources.)

2010; Young, 2012) and pigments (Cotte *et al.*, 2007, 2008, 2010; Dik *et al.*, 2008; Herrera *et al.*, 2009). Synchrotron-based experiments can also be combined with three-dimensional imaging (computed micro-tomography, μCT) and designed for the tomographic reconstruction of the diffraction signal (Bleuet *et al.*, 2008); the technique is defined as X-ray diffraction microtomography (XRD-μCT: De Nolf & Janssens, 2010; Artioli *et al.*, 2010; Valentini *et al.*, 2011) and it is an example of the increasing potential of the combination of diffraction and imaging techniques. Specific software is publicly available for the analysis of two-dimensional multi-spectral signals (*PyMCA – Python Multichannel Analyzer*: http://pymca.sourceforge.net/index.html; Solé *et al.*, 2007) and also for three-dimensional tomographic reconstructions using the diffraction signal (*XRDUA*: http://xrdua.ua.ac.be/; De Nolf & Janssens, 2010).

Thermal neutron beams, both from spallation sources and from steady-state nuclear reactors, by virtue of their penetration power (Table 7.4.1) are ideal for the analysis of large and thick objects. *Neutron imaging* is a leading technique for the internal visualization of art and archaeological objects (Lehmann *et al.*, 2005, 2010; Casali, 2006), and it is increasingly coupled with diffraction probing of the materials to obtain simultaneous complete information of phase composition and heterogeneous distribution of materials within the objects (van Langh *et al.*, 2011). Novel neutron-imaging techniques, sometimes called Bragg-edge imaging (Lehmann *et al.*, 2009), are being developed in order to enhance the phase sensitivity of the tomographic images (Kockelmann & Kirfel, 2006; Kockelmann *et al.*, 2006).

Both in the case of synchrotron microbeams and in the case of enhanced neutron imaging, it is expected that in the near future the powerful combination of imaging and diffraction will be a major tool in cultural-heritage research. Furthermore, synchrotron and spallation neutron beams allow experimental access to extended scattering space, so that the rapidly developing techniques based on pair-distribution functions (PDFs) that make use of total scattering for structure analysis can be efficiently employed (Welberry, 2004; Egami & Billinge, 2004). These techniques can equally be applied to crystalline and disordered materials and, although they have not yet been applied to cultural-heritage materials, they offer great potential for future contributions.

In honouring the past 100 years (1912–2012) as the period in which diffraction has developed into an important and mature characterization technique, we can not avoid recalling the huge instrumental developments that have occurred in the last decades. Should the technical and methodological developments proceed at the same pace, we will soon have many more tools available for the investigation of our past heritage.

As a final remark, it is advised that use of the cited diffraction techniques, from portable sources to advanced large-scale synchrotron radiation and neutron sources, are inserted into appropriate analytical protocols. Ranking the experimental operations in terms of increasing cost and manpower, the ideal analytical sequence involving diffraction might encompass: (*a*) a first qualitative step based on preliminary sampling and/or portable instrumentation; (*b*) a second quantitative step based on appropriate (micro)sampling, *in situ* analysis, and/or laboratory quantification; and (*c*) a third step exploiting experiments at large-scale facilities for improved data quality and access to non-standard instrumentation and techniques.

7.5. Powder diffraction and pharmaceuticals

J. Bernstein and S. M. Reutzel-Edens

7.5.1. Introduction

X-ray powder diffraction (XRPD) plays an important, if not crucial, role in the pharmaceutical industry. In much of the world, the vast majority of pharmaceutical products are administered as solids in various forms – generally as tablets or capsules, but even in many cases when administered *via* inhalation, as suppositories, by parenteral injection or topically, the characterization and control of the solid-state properties of the active pharmaceutical ingredient (API) are of prime importance in the formulation of the final product. In this chapter, pharmaceutical solids will include crystalline materials (*i.e.* polymorphs, solvates, hydrates and co-crystals) as well as amorphous materials. As highlighted in Fig. 7.5.1, solid-state science and technology is applicable to virtually every aspect of the pharmaceutical industry and, as a principal tool in solid-state research, XRPD plays a key role in many aspects of that industry. In fact, X-ray powder diffraction is usually considered the 'gold standard' for the identification and characterization of pharmaceutical solid materials. This chapter will describe and provide examples of some of the important applications of powder diffraction in the various stages of pharmaceutical research and development, from initial identification of a potential API through the lifetime of a marketed product.

7.5.2. Some basic background and references

Because it has long been recognized as an important analytical tool for the identification and characterization of solids, a great deal has been written about the applications of X-ray powder diffraction in the pharmaceutical industry. The fundamentals of modern powder diffraction may be found in the classic text by Klug & Alexander (1974) and in more recent books by Jenkins & Snyder (1996*a*) and Lifshin (2008). Applications to the pharmaceutical industry are discussed, for instance, by Byrn *et al.* (1999), Bernstein & Henck (2000) and Ivanisevic *et al.* (2010), or in many of the chapters of the multi-authored volumes authored or edited by Hilfiker (2006), Hilfiker & von Raumer (2018) and Brittain (1999, 2009). The annual summaries by Brittain (*e.g.* Brittain, 2011) provide continuing examples of the application of X-ray powder diffraction to polymorphic and solvatomorphic pharmaceutical materials, either as a single analytical technique or, increasingly often, in combination with other analytical techniques – a strategy which is definitely to be encouraged.

The utility of powder diffraction in the pharmaceutical industry can be demonstrated by examining applications from the various stages of drug development, manufacturing and marketing, and establishing and protecting intellectual property. Owing to space limitations and the vast variety of problems that can be and have been tackled using XRPD, only a small selection is given here, with the intent that this snapshot can provide a picture of the central role of XRPD in the pharmaceutical industry.

7.5.3. Identification and characterization

7.5.3.1. *Polymorphs, salts, solvates, co-crystals*

The choice of the solid form of the API for a pharmaceutical product involves many facets of the discipline of organic solid-state chemistry (Pulacki *et al.*, 2010; Henck & Byrn, 2007). The selection of the solid form from among the possible salts, co-crystals, solvates and other solid forms of the drug, accompanied by knowledge of their physical properties, can reduce the development time to successful clinical trials, balance risk in subsequent pharmaceutical development and ultimately reduce the costs of making new drugs accessible to the patient. An understanding of the molecular structure of an active pharmaceutical ingredient (API) in the solid state and the use of a particular solid form can lead to better design and control of drug performance. Nowadays it is clearly understood that early engagement with the pharmaceutical development scientist on the identification of an optimal solid form and formulation during the drug-discovery stage can lead to significant benefits throughout the drug-development process. Solid forms such as different polymorphs of an API, hydrates or solvates, as well as salts, co-crystals and amorphous materials, including amorphous dispersions, need to be considered in this context. These different forms can show variations in the physical or chemical characteristics of a given API, such as solubility, bioavailability or stability. One of the most important benefits of early identification of solid forms is the potential for reducing pre-clinical candidate attrition and proceeding to *in vivo* studies more quickly; these studies can potentially demonstrate dose-limiting toxicity in order to establish acceptable and reproducible safety margins in

pre-clinical toxicity studies. Timely identification of an optimal solid form can also minimize the need to change the solid form of an API during drug development, which in turn reduces costs of *in vitro* physicochemical studies and *in vivo* comparison studies. However, early optimization of the solid form of the API is just one aspect of a targeted drug-development strategy. Many other factors play an important role in whether or not a given API can be brought to the market successfully. It is clearly understood that crystalline materials exhibit properties that derive from both the molecular structure and from the arrangement of the molecules within the solid form; thus changes in the placement and/or interactions between the molecules resulting from a different solid-state structure usually have a direct impact on some or all of the properties of the particular solid (Grepioni & Braga, 2007). Today, solid-state chemists call upon a variety of different strategies when attempting to alter the chemical and physical properties of a given API; these typically include the formation of salts, co-crystals, polymorphs (including polymorphs of salts and co-crystals), amorphous materials (including amorphous dispersions), hydrates and solvates. Amorphous dispersions, where an amorphous API is embedded within a polymer matrix, also provide a viable solid-state route that sometimes leads to improved solubility and potentially improved bioavailability in comparison to the crystalline API. However, amorphous materials are inherently thermodynamically less stable than their crystalline counterparts, and thus are typically not the first solid form of a given API to be selected. Likewise, although thermodynamically metastable crystal forms of a given API usually have the potential benefit of being more water soluble relative to the thermodynamically stable crystal form at room temperature, these form(s) are typically not preferred in pharmaceutical development because of the risk of transformation into the stable form during pharmaceutical processing.

One primary route to a suitable solid form is the preparation of a salt, and it is estimated that over half of the medicines on the market are administered as salts (Stahl & Wermuth, 2002). However, a necessary criterion for this approach is that the API possesses a suitable ionizable site. Co-crystals, however, offer a different pathway, where any API, regardless of whether it is acidic, basic or non-ionizable, can potentially be co-crystallized with either an inert compound or one which can serve as an additional therapeutic agent. The efforts of the pharmaceutical industry over the last 15 to 20 years to invent new compounds to be used as APIs have led to more and more compounds with limited water solubility and bioavailability. It has been estimated that approximately 40% of marketed products and up to 75% of compounds under development are poorly water-soluble and belong to class 2 or class 4 of the biopharmaceutical classification system (Williams *et al.*, 2013). Class 2 compounds show low solubility and high permeability, whereas class 4 compounds exhibit low solubility and low permeability. Therefore, class 2 compounds are of particular interest in the context of salts and co-crystals (and amorphous dispersions), because improving the apparent solubility (a combination of dissolution and solubility) of a given material *via* formation of a co-crystal or salt may be a useful and successful strategy for improving bioavailability. Other properties of an API that could potentially be altered by forming a co-crystal or salt are the melting point, hygroscopicity, physical and chemical stability, filterability and colour, as well as crystallinity. It should be made clear that no one particular strategy improves the properties of all APIs. Each API must be examined and evaluated on a case-by-case basis in terms of molecular structure and the desired final properties (Amidon *et al.*, 1995). In addition, there is no guarantee that the particular property of interest will be altered, as we still lack the ability to predict the changes that might result in the properties of a compound due to a change in crystal form.

XRPD is the analytical tool that is most closely related to the crystal structure. The different solid forms of any given compound exhibit different X-ray powder diffraction patterns that be used to uniquely identify them. Structural information for solids can also be derived from powder X-ray diffractometry. Even upon identification and choice of a lead compound for further pharmaceutical development, it is usually highly advisable to survey the crystal-form landscape to get some idea of the number and characteristics of the polymorphs, solvates and hydrates that might exist for that compound. Such a survey can never be considered complete, especially in the early stages of development, since new crystal forms are often discovered, even serendipitously, well into development or even after launch (Hilfiker & von Raumer, 2018), but an appropriate screen can often provide crucial information about the ultimate choice of crystal form and the difficulties that might be encountered in obtaining that form consistently and robustly (Bernstein, 2019; Braga & Bernstein, 2007; Morris, 1999; Griesser, 2006; Byrn *et al.*, 1999).

Efforts to survey the crystal-form landscape as completely as possible also have important implications for intellectual-property rights. A familiarity with the landscape can extend the breadth of the intellectual property of the innovator; on the other hand, the development or discovery of new solid forms in the landscape can offer the opportunity to circumvent existing patent protection. In this regard, the continuing development of crystallization platforms is particularly noteworthy (Morissette *et al.*, 2004; Kumar *et al.*, 2007), and the availability of automatic sampling and measuring systems for X-ray powder diffraction (*e.g.* Beckers, 2008) has made it increasingly feasible as an efficient screening technique. While high-throughput screening techniques facilitate the survey of the crystal-form landscape, they are by no means routine. The choice of solvent, or solvent combinations, heating and cooling cycles, degree of supersaturation and a variety of other conditions lead to a virtually infinite array of possibilities. It is therefore crucial to develop strategies based on a preliminary assessment of solubility properties and also phase behaviours using techniques such as hot-stage microscopy and thermal methods [differential scanning calorimetry (DSC), thermogravimetric analysis (TGA)].

7.5.3.2. *Indexing*

An indexed powder pattern is a unique identifier of a solid material. While an XRPD pattern may be considered as the fingerprint for a particular solid, indexing its powder pattern does not, in itself, guarantee that the pattern is of a pure material. Ivanisevic *et al.* (2010) have provided an overview on how indexing can be used to generate structural information from XRPD patterns collected using standard laboratory X-ray equipment. Indexing is the process of determining the size and shape of the unit cell from the peak positions in the XRPD pattern. The term *indexing* is derived from the assignment of Miller index labels to individual peaks. Determining the lattice parameters of the unit cell from XRPD data requires knowledge of how to assign the Miller indices h, k, l to each diffraction peak. For a known material, this is done by comparing the data to those reported in the literature or found in a database such as the International Centre for Diffraction Data (ICDD) Powder

Diffraction File [PDF-4+ (2018); http://www.icdd.com], or to data generated from a known crystal structure from, for example, the Cambridge Structural Database [Groom *et al.* (2016); https://www.ccdc.cam.ac.uk]. The Miller indices relate the peak positions or *d*-spacings to the lattice parameters by an equation specific to the crystal system. The various indexing strategies and procedures are described in detail in Chapter 3.4.

Successfully indexing an XRPD pattern offers multiple benefits. If all of the peaks in the XRPD pattern are indexed using a single unit cell, this can be regarded as strong evidence that the sample contains a single crystalline phase. The unit-cell volume may then be calculated and if the chemical composition and therefore the molecular mass of the sample is known, the true density of the material can also be calculated accurately. Another important potential benefit of indexing a pattern is that it can be taken to show that an XRPD pattern is consistent with the structure determined by single-crystal X-ray diffraction, so that the two are representative of the same solid material. Examples of indexing programs and tools that are available either in the public domain or commercially and are widely used in the pharmaceutical field include *TREOR* (Werner *et al.*, 1985), *N-TREOR* (Altomare *et al.*, 2000), *X-CELL* (Neumann, 2003), *DICVOL* (Boultif & Louër, 2004), singular value decomposition (Coelho, 2003) and *TOPAS* (Bruker AXS, 2008).

7.5.3.3. *Crystal structure solution*

Crystal structure determination is a key component of studies relating the solid-state chemistry of drugs to their ultimate use in medicinal products. The connection between internal crystal structure, particle properties, processing and product performance, which collectively form the materials science tetrahedron (Sun, 2009), would be nearly impossible to draw without access to three-dimensional crystal structure information derived from X-ray diffraction. While single-crystal X-ray diffraction is unequivocally the most definitive and preferred technique for crystal structure determination, quite often suitable single crystals cannot be grown to sufficient size (of the order of ~100 µm) or quality for the classical approach to be taken. For example, rapid crystallization of metastable crystal forms, dehydration of hydrates and mechanical grinding, all common to the pharmaceutical industry, are capable of producing highly diffracting materials, but only as powders. In such cases, XRPD is increasingly used to solve the crystal structures of the component phases.

The determination of crystal structures from powder diffraction data, which is detailed in Part 4 of this volume, generally involves three steps: (1) indexing the peaks in the experimental pattern to determine the size and shape of the unit cell, along with the space-group symmetry; (2) using the diffraction peak intensities to generate a good approximation of the atomic positions in the crystal structure; and (3) refining (usually by the Rietveld method) the trial structure to fit the simulated XRPD pattern of the model to the full experimental powder pattern. Of all of the steps in the powder structure solution process, the initial determination of the lattice parameters tends to be the most problematic. Indexing solutions identified based on the molecular volume, cell volume and number of unindexed reflections (see Chapter 3.4) are therefore usually checked using either Le Bail (Le Bail *et al.*, 1988) or Pawley (Pawley, 1981) fitting (see Chapter 3.5). With input of the chemical structure, the unit-cell parameters and space group, trial crystal structures are next generated in direct or real space. Search algorithms, some implemented in commercially available programs, *e.g. DASH* (Shankland *et al.*, 2006), *TOPAS* (Coelho, 2000, 2003) and *PowderSolve* (Engel *et al.*, 1999), vary the positions, orientations and internal degrees of freedom of molecular fragments within a unit cell until a match between the simulated and experimental XRPD patterns is obtained. The resulting structure model, along with peak profile and background parameters, displacement parameters, zero-point error, and preferred orientation, are refined by the Rietveld method in the third and final stage to improve the accuracy of the structure solution, as shown for fexofenadine hydrochloride in Fig. 7.5.2.

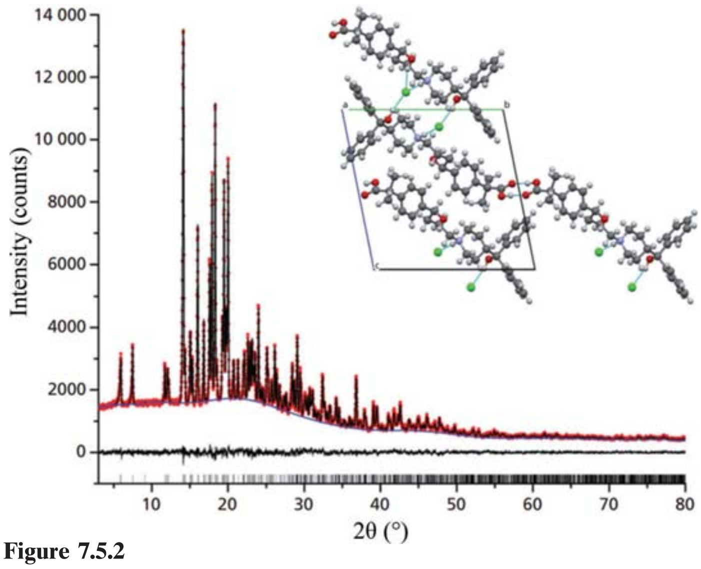

Figure 7.5.2
Profile plots for the Rietveld refinement of fexofenadine hydrochloride. Experimental data are shown as red dots, simulated data as a black line. The difference curve, along with tick marks representing the theoretical peak positions, are shown below. [From Brüning & Schmidt (2015) adapted with permission from John Wiley and Sons.]

The information that is inevitably lost when three-dimensional diffraction is compressed into a one-dimensional powder pattern generally increases the difficulty and uncertainty of structure solution from powders. Measures taken to ensure that the structure model is as accurate and precise as possible include carefully preparing highly crystalline, preferably phase-pure powders in thin-walled capillaries or between polymer films, and collecting data in transmission mode, while spinning the sample to both minimize preferred particle orientation effects and achieve good powder averaging (see Chapter 2.10). For the high accuracy needed for structure solution, the experimental diffraction pattern is typically measured over a wide 2θ range, usually up to 70 or 80°. The powder structure solution is assessed at the final Rietveld refinement stage (Chapter 4.7) by comparing its calculated powder pattern with the experimental pattern, the fit being qualitatively visualized by the difference curve (the black curve at the bottom of Fig. 7.5.2) and quantified by either a weighted powder profile R factor ($R_{\rm wp}$) or full profile χ^2. Dispersion-corrected density functional theory (DFT-D) energy minimization is often used to verify that crystal structure solutions are correct, given by a root-mean-square displacement (r.m.s.d.) of the atomic coordinates of 0.35 Å or less (van de Streek & Neumann, 2014).

7.5.4. Quantitation of mixtures by traditional and Rietveld methods

Given that the different solid forms (crystalline and amorphous) of a compound may perform differently in a drug product, validated quantitative methods may be required to ensure control of the manufacturing process. This is particularly the case when mixtures of forms known to have different chemical stabilities or physical properties that are relevant to drug product performance cannot be avoided. If a quantitative method is required, whether for quality control, process understanding or demonstrating patent infringement, X-ray powder diffraction can, under carefully controlled conditions, provide accurate quantitative information on *crystal form purity* (as distinguished from *chemical purity*). Quantitative phase analysis of crystal forms, as well as the assessment of the degree of crystallinity, by X-ray powder diffraction have been extensively reviewed (Jenkins & Snyder, 1996*b*; Stephenson *et al.*, 2001). Here we describe the basic elements of quantitative analysis by powder diffraction, highlighting applications in the pharmaceutical industry.

Quantitative phase analysis by X-ray powder diffraction is based on the assumption that the diffraction intensity for a component mixture is related to the proportion of each component in the mixture. The basic elements of quantitative analysis of powders from XRPD pattern intensities were initially outlined by Alexander & Klug in 1948. The general expression used for quantitative diffraction analysis of a two-component (α and β) system is

$$I_{(hkl)\alpha} = \frac{KX_\alpha}{\rho_\alpha[X_\alpha(\mu_\alpha^* - \mu_\beta^*) + \mu_\beta^*]},$$

where $I_{(hkl)\alpha}$ is the intensity of the *hkl* reflection of the α component, K is the proportionality constant given by physical parameters related to the experimental setup and specific to each *hkl* reflection, ρ_α and X_α are the density and weight fraction of component α, respectively, and $\mu_\alpha{}^*$ and $\mu_\beta{}^*$ are the mass attenuation coefficients of components α and β, obtained by dividing the linear attenuation coefficient, μ, by the component density. For the special case of polymorph mixtures or mixtures of crystalline and amorphous phases, where $\mu_\alpha{}^* = \mu_\beta{}^*$, the expression is simplified and the relative intensity of a given peak will be directly proportional to the phase concentration. For other physical mixtures, including formulations, where the mass attenuation coefficients of the analyte (α) and matrix (collectively described by β) are likely to be different, the relative peak intensity may not vary linearly with concentration. In cases where the elemental composition is known, $\mu_\alpha{}^*$ and $\mu_\beta{}^*$ may be calculated from published elemental mass attenuation coefficients. Although not extensively used in the pharmaceutical industry for quantitative phase analysis, this absorption method can be used to extract quantitative phase information, as has been demonstrated for carbamazepine (Suryanarayanan, 1989).

Traditional quantitative X-ray powder diffraction methods more usually rely on calibration curves constructed using internal standards, avoiding corrections based on mass attenuation coefficients. Internal-standard methods may be based on peak intensities (heights), relative peak-intensity ratios or integrated peak areas, and either individual peaks or whole patterns may be used to relate peak (or whole-pattern) intensities to the amount of each phase present. When examination of the diffraction patterns of the component phases reveals sufficient selectivity for a particular form, simple univariate quantification methods based on XRPD peak heights or areas may be appropriate. Whole-pattern methods, on the other hand, combine analysis of both Bragg diffraction and diffuse scattering, allowing for better definition of overlapping peak intensities, as well as improved background fitting. With whole-pattern methods, the diffraction patterns of the sample (unknown) and reference (component) phases are recorded as digitized intensity values, allowing the full diffraction pattern of the unknown to be reconstructed as a weighted sum of the diffraction patterns of the component phases. Multivariate chemometric techniques, including classical least-squares (CLS) regression, principal-component regression (PCR) and partial least-squares (PLS) regression, can be used to improve the correlation between predicted and measured compositions, as has been demonstrated for pharmaceutical compacts of theophylline (Moore *et al.*, 2009).

The Rietveld method (Rietveld, 1967), originally used for crystal-structure refinement, has evolved as an *ab initio* quantitative method for phase analysis. As in other whole-pattern methods, the Rietveld method involves point-by-point least-squares fitting of the entire experimental diffraction pattern with a calculated profile of a model constructed from known component phases. With the Rietveld method, however, the model of the diffraction pattern is first built, then matched to the experimental pattern by refining the lattice parameters, profile shape, scale factors, background coefficients, and in some cases the atomic positions and site occupancies, for each component phase. The scale factors defining the relative amounts of each component are adjusted to match the model to the experimental data until good agreement is obtained. Rietveld analysis, like other whole-pattern fitting methods, is a standardless method in the sense that it does not use a calibration curve, but it does require a structural model (lattice parameters, space-group symmetry, atomic positions, site occupancies) of each phase being analysed, from which a powder pattern can be simulated. Here it should be recognized that for pharmaceutical materials, single-crystal structure determination is often performed at low temperatures for increased accuracy, and it is becoming increasingly common to use 0 K structure models derived from *ab initio* crystal structure prediction calculations as inputs to Rietveld refinements. If low-temperature structures (or computed 0 K structures) are used, the possibility of unit-cell contraction, which will increase the scale factor, must be considered. In such cases, the unit cell, displacement parameters and scale factor will require adjustment in the refinement. An ICDD-sponsored round robin highlighted many of the challenges in quantitative phase identification using the Rietveld method, but demonstrated that in the hands of the experienced practitioner, accurate quantitative analysis (with errors of the order of 5–10%) is possible (Fawcett *et al.*, 2010). Shown in Fig. 7.5.3 is a successful application of the Rietveld method for the quantitative phase analysis of heat-treated carbamazepine (Antonio *et al.*, 2011). In this example, an improved fitting was achieved by accounting for a form-III phase impurity in a sample otherwise of form I.

To ensure that measured diffraction peak intensities (or areas) are proportional to the amounts of the different phases that are present, potential sources of error from the sample itself, the sample preparation and the instrument must be considered. The typically large unit cells and low symmetry of pharmaceutical compounds often lead to peak congestion. In drug product formulations, the dilution of the drug with large quantities of excipients and overlapping diffraction peaks can be especially problematic. Organic compounds tend to have low mass-absorption coefficients, leading to deep (of the order of mm) X-ray beam penetration into the sample, which can cause diffraction-line shifting. Diffraction peak intensities are strongly influenced by preferred crystallite orientation, packing density and the homogeneity of the sample. For hygroscopic materials, where the diffraction patterns change as a function of water

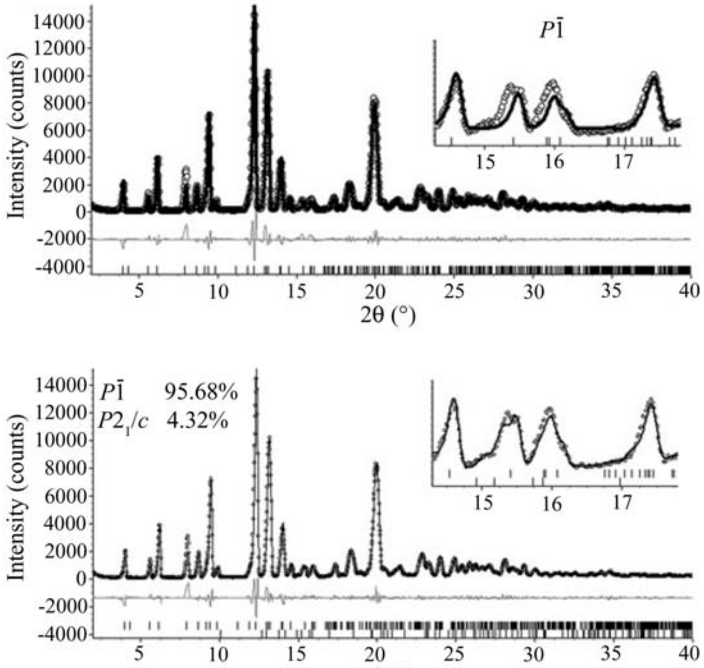

Figure 7.5.3
Profile plots of the Rietveld refinement of heat-treated carbamazepine, showing an improved fit over pure form I (space group $P\bar{1}$, top) obtained by modelling the X-ray powder diffraction pattern with ∼4% form III (space group $P2_1/c$) in form I (bottom) [from Antonio *et al.* (2011) with permission from John Wiley and Sons].

content, peak intensities may further depend on the relative humidity.

Quantitative diffraction methods depend upon obtaining an experimental powder pattern uncomplicated by the effects of preferred orientation, extinction, microabsorption, variable packing density and sample inhomogeneity. To avoid preferred orientation altogether requires sampling truly random orientations of crystallites, which can be difficult to achieve in practice. Common approaches to minimizing the effects of preferred orientation include collecting XRPD data in transmission geometry, particle-size reduction and sample back-filling. Whether or not preferred orientation has been minimized successfully can be determined by comparison of the experimental diffraction patterns to patterns of the components that have been calculated from single-crystal data, when available. Extinction and microabsorption effects will become negligible only when the particle size is sufficiently small. To this end, numerous techniques are available to reduce particle size; however, care must be taken to avoid phase transformations during comminution. In order to even out differences due to packing density, a specific sample weight and compaction pressure is often used to prepare samples for XRPD analysis. As sample homogeneity (sub-sampling) can also compromise the accuracy of quantitative analysis by XRPD, dry mixing and, in some cases, slurrying or sonicating in a non-solvent are used. For the latter method, the solvent of crystallization may be preferred for homogenizing solvates that are at risk of being desolvated or exchanged in suspensions of other solvents. Sample rotation is also generally recommended during XRPD analysis to improve counting statistics.

As with any quantitative assay, the validation of the XRPD method requires that range, specificity, linearity, accuracy, precision (repeatability) and ruggedness are demonstrated and the limit of quantitation (LOQ) and limit of detection (LOD) are firmly established. Range, specificity and linearity are demonstrated by a calibration curve. The LOQ and LOD are typically calculated according to the International Conference on Harmonization guidelines (ICH, 1996) as $10\sigma/S$ and $3.3\sigma/S$, respectively, where σ is the standard deviation from multiple measurements of the pure component (or a defined mixture of components) and S is the slope of the calibration curve. XRPD calibration models constructed for multivariate methods require the preparation of calibration samples, which must not only account for the multi-phase nature of the pharmaceutical system, but also be sufficiently robust to accommodate variability in the diffractograms. Method validation relies on prepared samples specifically not included in calibration data sets to evaluate accuracy, repeatability and intermediate precision, as well as to demonstrate laboratory-instrument comparability. Quality indicators for quantitative calibration models may include the correlation coefficient (R^2), the test-set validation coefficient (Q^2), the root-mean-squared error of estimation (RMSEE) and the root-mean-squared error of prediction (RMSEP). With the appropriate controls, XRPD methods have been developed with accuracy, precision and reliability rivalling, and in some cases exceeding, those of quantitative spectroscopic methods (Német *et al.*, 2010), positioning XRPD well as the gold standard for both qualitative *and* quantitative phase analysis of pharmaceutical materials.

7.5.5. Characterization of amorphous materials

As noted above, crystalline forms of a drug are generally preferred over amorphous forms, as they confer exquisite control over the physicochemical properties affecting drug product quality, safety and performance. However, when a material fails to crystallize, the only choice may be to proceed with an amorphous form. Additionally, with the ever-increasing number of poorly soluble new chemical entities in drug development, amorphous solids are increasingly being used in the hope of improving dissolution-rate-limited absorption. Amorphous forms designed to enhance bioavailability are commonly prepared, often in the presence of polymeric nucleation inhibitors, using techniques such as spray drying, lyophilization and melt extrusion. Amorphous or glassy phases may also be generated, albeit unintentionally, during high-energy processes such as milling or micronization, compaction and wet granulation (Yu, 2001). Crash precipitation or exposure of a drug crystal form to drying or storage conditions under which desolvation may occur has the potential to introduce disorder as well. Whether amorphous forms are encountered by default (when a substance is inherently noncrystalline), by design (when a substance is rendered amorphous through kinetic trapping) or by accident (when a substance is inadvertently rendered amorphous by mechanical or thermal stress), disorder can compromise the physical and chemical stability of solid drugs and is therefore important to understand and control (Ahlneck & Zografi, 1990).

X-ray powder diffraction has been widely used to assess crystallinity in pharmaceutical materials. Whereas crystalline phases possessing long-range order produce sharp Bragg diffraction peaks, X-ray amorphous materials are generally characterized by a raised baseline or 'halo' in their diffraction patterns. The characterization of sample crystallinity is complicated by the fact that amorphization or the loss of long-range order may occur under various processing or storage conditions throughout the bulk solid or predominantly at the surface of crystalline particles. As different types of disorder affect the physical and chemical properties of a drug substance in different

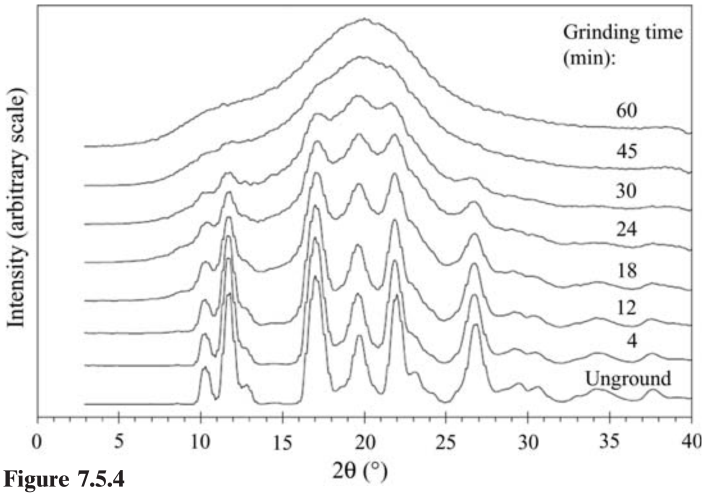

Figure 7.5.4

X-ray powder diffraction patterns of indomethacin, showing progressive loss of long-range order (crystallinity) with extended grinding. Within 60 min, a broad halo is formed as indomethacin is rendered X-ray amorphous. Reprinted by permission of Springer Nature from Bates *et al.* (2006). Copyright (2006).

ways and to different extents, the strategy used for characterization should account for the nature of the crystal imperfections or amorphous material.

It is important to distinguish here between, on the one hand, various types of disorder in a crystalline material that exhibits long-range order, and on the other hand an amorphous material. The distinction is described in detail in Giacovazzo *et al.* (2011). In the current context, for instance, the disorder of an aliphatic carbon chain in the pharmaceutically important compound ranitidine hydrochloride (Zantac) has been accounted for by a Rietveld refinement against synchrotron powder diffraction data (Huq & Stephens, 2003).

To assess the degree of crystallinity of a given sample accurately by accounting for the different types of disorder, partially ordered systems have been described using either ‘one-state’ or ‘two-state’ models (Hancock & Zografi, 1997). In the one-state model, amorphization is distributed throughout the bulk particles and domains are truly partially crystalline (Rani *et al.*, 2006). X-ray powder diffraction can be used to detect the accumulation of crystal defects that characterize partially crystalline one-state systems; however, other techniques, such as DSC or solid-state NMR spectroscopy, are commonly used in conjunction with XRPD to examine this type of disorder. In the two-state model, domains within a material are assumed to be either 100% amorphous or 100% crystalline and to coexist side-by-side in a physical mixture. The two-state model best characterizes surface amorphization as exemplified by indomethacin (Bates *et al.*, 2006), where the integrated intensity of background scattering in the diffraction pattern coming from the disordered (amorphous) phase increases at the expense of the diffraction peaks of the ordered (crystalline) phase upon continued grinding (Fig. 7.5.4).

By assuming that crystalline and amorphous components coexist as a phase-separated mixture (two-state model), partially crystalline materials may be simulated using physical mixtures of crystalline and amorphous reference materials with the extent of disorder in some cases being characterized by straightforward application of a calibration curve. Defining representative crystalline and amorphous standards can be difficult, however. Lattice defects are almost always present in crystalline materials, whether from the crystallization process or subsequent downstream processing (*e.g.* milling). Likewise, the background scattering of the amorphous phase will be affected by short-range order, which is not always easy to eliminate, and, in some cases component miscibility, which can cause the amorphous halo to change shape. In cases where the X-ray scattering pattern of multi-component amorphous systems cannot be described as a linear combination of the pure amorphous component diffraction patterns (Newman *et al.*, 2008), representative calibration samples may be generated by mixing the crystalline component with the combined amorphous matrix (Rumondor & Taylor, 2010). Once well defined crystalline and amorphous standards are in place, the degree of crystallinity may be determined by measuring either integrated diffraction peak intensities (or heights) or the intensity of amorphous scattering. Here, it is generally recognized that detecting the diffuse scattering of low levels of disorder in a mostly crystalline material is more difficult than detecting low levels of crystallinity (Bragg diffraction peaks) in an otherwise amorphous sample. Nonetheless, conventional X-ray powder diffraction has been used to quantify noncrystalline material down to levels of 5% with an absolute accuracy of ±3% (Byard *et al.*, 2005).

X-ray amorphous solids are characterized by the lack of Bragg diffraction peaks in their powder patterns, but the structure of these materials is not necessarily random. In fact, amorphous small-molecule materials often possess short-range order (less than 20–25 Å) extending to distances of the order of a few molecules or less. Traditional X-ray diffraction methods, which are powerful for identifying samples as X-ray amorphous and for characterizing the degree of crystallinity (long-range order) in partially crystalline materials, are of limited use for probing local (nanoscale) order in amorphous solids. However, atomic pair distribution function (PDF) analysis of powder diffraction data, which has long been used to study inorganic materials, has been applied to highly disordered and nanocrystalline pharmaceutical solids (Bates *et al.*, 2006), providing structural information that is otherwise inaccessible by the more established crystallographic techniques.

PDF is a total diffraction approach (the Bragg peaks and diffuse scattering are analysed together) used to study relationships between ordered and disordered systems by providing a fingerprint of interatomic distances, more specifically a weighted probability of finding two atoms separated by a distance r within a solid (Egami & Billinge, 2003). A PDF is generated by performing a Fourier sine transformation of the total scattering function $S(Q)$, the reduced structure-factor representation of a powder pattern measured in 2θ. As shown in Fig. 7.5.5 (Bøtker *et al.*, 2012), PDF data are generally presented as the probability, $G(r)$, of a given atom separation plotted as a function of distance r in Å. At sufficiently high resolution, interatomic distances may be accurately determined at each peak maximum in the PDF. Multiplying the amplitude of each peak with the corresponding distance further yields the number of atomic pairs separated by that distance.

The PDF analysis of crystalline, highly disordered and nanocrystalline pharmaceutical solids is illustrated for amlodipine besylate anhydrate (AH), dihydrate (DH) and milled (M) and quench-cooled (Q) samples in Fig. 7.5.5. Note the greater attenuation of the PDF trace of the Q material relative to the M material, which indicates a higher degree of disorder in the quench-cooled sample. These data, collected to 40° 2θ on a conventional laboratory diffractometer using low-resolution Cu $K\alpha$ radiation, were able to differentiate the local molecular-packing arrangements in the milled and quench-cooled amorphous samples, though they were not sufficiently accurate to

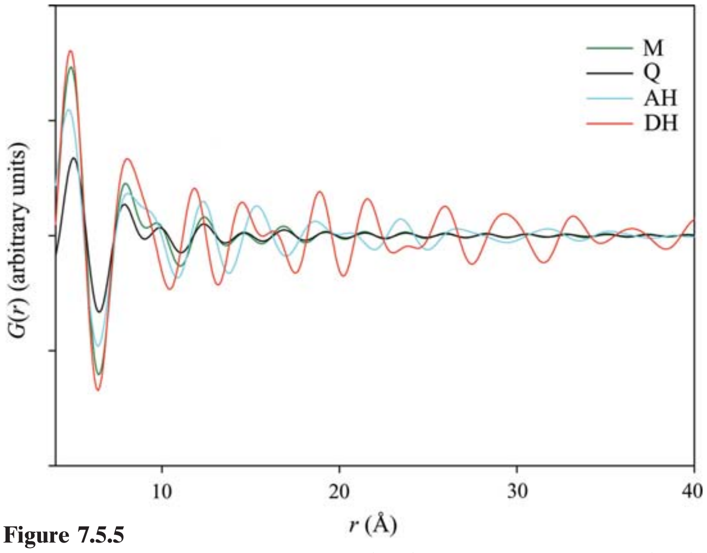

Figure 7.5.5
PDF traces of crystalline anhydrate (AH), crystalline dihydrate (DH), milled (M) and quench-cooled (Q) samples of amlodipine besylate [from Bøtker *et al.* (2012)].

relate the short-range order in the X-ray amorphous materials to structural features in the crystalline AH and DH forms.

To provide useful insights into local packing arrangements in noncrystalline materials across a wide range of *r* or at least to ensure that reliable fingerprints of amorphous pharmaceuticals are obtained, it is highly recommended that diffraction data used for PDF analysis are collected with low instrument background and good counting statistics to high momentum-transfer (*Q*) values. Synchrotron radiation can, of course, be used for this purpose (Billinge *et al.*, 2010); however, reliable high-resolution data are also achievable using laboratory diffractometers equipped with Ag or Mo sources (Dykhne *et al.*, 2011). With proper data collection, corrections (background scattering, sample absorption, polarization *etc.*) and normalization to account for instrument and sample effects, high-quality, physically meaningful PDF results can be obtained.

Interest in PDF analysis for the molecular-level characterization of pharmaceutical solids that are X-ray amorphous has grown rapidly in the pharmaceutical community. Applications range from fingerprinting amorphous forms (Dykhne *et al.*, 2011), following the evolution of structural disorder during processing and storage (Bates *et al.*, 2007) and characterizing the average particle size of nanocrystalline materials (Billinge *et al.*, 2010) to examining phase separation in amorphous dosage forms (Newman *et al.*, 2008). Another area of interest that relies on extracting detailed structural information is the identification of residual polymorphic 'memory', which can lead not only to batch-to-batch variability in materials rendered amorphous by milling, but also direct the crystallization of a particular polymorphic form from the amorphous state (Sheth *et al.*, 2005).

7.5.6. Quality control and regulatory aspects

The US Food and Drug Administration (FDA), recognizing that the presence of different crystalline forms has the potential to alter drug product quality and performance, have published guidance for setting acceptance criteria for new drug substances and drug products produced from them. The International Conference on Harmonization (ICH) Guidance on Q6A Specifications (ICH, 1999) specifically states that when physical-property differences between forms are shown to affect drug product performance, bioavailability or stability, the appropriate solid state should be specified. The choice of which analytical technique to use in support of setting material specifications is left to the applicant and will largely depend on identifying one that is both suitably discriminating and amenable to use in a quality-control (QC) setting. As a technique that is generally selective, relatively inexpensive and easy to implement, and allows for rapid and reliable analysis, XRPD is widely used in QC laboratories for the purpose of both fingerprinting incoming raw materials and release testing final products. It is generally accepted that when the manufacturing process for a drug substance consistently delivers a single solid-state form, qualitative 'identity' testing should be sufficient. However, in cases where a manufacturing process produces more than one solid-state form with the potential to affect drug product quality, safety or performance, validated quantitative methods may be required to ensure that the forms are produced in fixed proportion.

Today's regulatory environment has been further shaped by FDA guidance (ICH, 2009) advocating that quality be built into drug products by design as opposed to being tested into them. A key driving force for introducing new and efficient manufacturing technologies into the pharmaceutical industry was the appreciation that many process and product failures have resulted from poor understanding and control of crystallization processes. For a pharmaceutical crystallization process to consistently deliver a drug substance with the desired qualities, of which crystal form is paramount, the use of both process analytical technology (PAT) (Yu *et al.*, 2004) and quality by design (QbD) principles (Yu, 2008) has been encouraged. Online PAT tools are generally preferred as they allow for real-time process monitoring, and near infrared and Raman spectroscopy, in combination with chemometric methods, have increasingly been used for monitoring crystal form in pharmaceutical production settings. XRPD technology has also been developed for *in situ* monitoring of form evolution and has been successfully applied to both slurry conversion (Dharmayat *et al.*, 2006, 2008) and wet granulation (Davis *et al.*, 2003) processing. These applications have shown great promise for designing robust crystallization and formulation processes in the laboratory, but further development is needed to realize the full potential of online XRPD for providing continuous, real-time assurance of quality in commercial drug-substance and drug product manufacturing.

7.5.7. Creating and protecting intellectual property

Intellectual property rights are protected by patents. The patents on pharmaceuticals are among the most important and most valuable in modern society. Despite continuing debates about the relative costs and benefits of pharmaceutical patents, there is general agreement that the incentive for the invention and development of new drugs is intimately connected to the intellectual property protection afforded by the patent system.

Patents are granted for inventions and give the grantee exclusive rights over that invention – that is, the right to prevent others from making it, using it or selling it. A patent is a social contract: in return for granting the inventor those exclusive rights, the inventor must teach the public how to use his or her invention when those rights have expired. Two of the fundamental criteria for the granting of a patent are that the invention must be *novel* and it must be *non-obvious* to the hypothetical person 'skilled in the art' defined, for example, by the European Patent Office, as one who 'should be presumed to be a skilled practitioner in the relevant field of technology, who is possessed of average knowledge and ability and is aware of what was common general knowledge in the art at the relevant date'. Finally, it must have some *utility*.

Novelty and obviousness are terms that are debated in virtually every legal confrontation about crystal forms. As pointed out earlier (Bernstein, 2019; Bernstein & MacAlpine, 2018), by definition essentially every new solid form is novel. Furthermore, for any compound it is not obvious – and not possible to predict – how many different solid forms can be prepared or how to prepare any, as yet unknown, solid forms, and it is not possible to predict the properties of any, as yet unknown, solid forms. It is virtually impossible to provide specifics beyond that general statement since every compound is a new situation and every legal jurisdiction has its own rules, regulations, legal framework and case law, but the novelty and non-obviousness of crystal forms means that virtually every new crystal form is potentially a patentable entity.

Utility is considered differently by US and European patent examiners. In the US an invention meets the utility requirement if it is capable of being used and provides some identifiable benefit. In Europe utility is not a criterion for patentability; rather the invention must have some industrial applicability. In the current context it might be noted that a less stable crystal form might have greater solubility and hence higher bioavailability or more rapid physiological absorption than the corresponding stable form.

Because of the (albeit limited-term) market exclusivity they provide, the patents on crystal forms for many drugs are the linchpins of commercial success. The role of XRPD in defining the inventions for the preparation of a patent application and in the subsequent protection of the patent against alleged infringement is often crucial. As noted above, the XRPD pattern of a solid material is generally viewed as a fingerprint and is often considered to be the gold standard for characterizing solid materials. Therefore, many patents on solid forms contain XRPD patterns/data of the claimed form(s), either as the only characterizing physical or chemical data, or along with IR, Raman, solid-state NMR and/or DSC/TGA data for further characterization.

It is important to distinguish here between the major components of a patent. Following a general *background* leading up to the invention described in the patent, the inventors then provide the *specifications* that summarize how to make the invention. In the case of a patent for a pharmaceutical solid form, the specifications will describe in a general way how that solid form is made and how it may be identified and characterized. This is generally followed by specific *examples* that *teach* the detailed procedure for obtaining the solid form(s), that is, *enabling* the person of skill in the art to *practice* the invention. The examples will usually contain the analytical techniques and characterizing data for the solid form(s).

Following the specifications, the actual invention in a patent (for the present discussion, a solid form) is defined by the *claim(s)* that are listed separately from the specifications (usually at the end of the patent), or a general description of the invention. Since the claims actually define the invention, proof of infringement of the patent requires providing conclusive evidence that the alleged infringer has made, used or sold the invention as defined in the claim. Thus the framing and interpretation of claims on crystal forms is often a crucial issue in patent litigations. In spite of the order in which these sections are presented to the public, it is often enlightening to read the claims first in order to determine the nature of the invention.

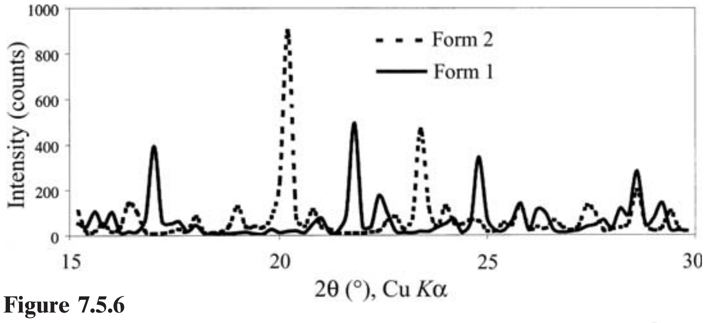

Figure 7.5.6
XRPD traces of the two pure forms of ranitidine hydrochloride [from Agatonovic-Kustin *et al.* (1999) with permission from Elsevier].

There is considerable freedom and hence considerable debate on how to present and define the XRPD pattern of a crystal form in a patent claim. Should the claim contain a graphical representation of the diffraction pattern or a complete or selected list of 2θ values (or equivalent *d*-spacings and intensities, relative or absolute)? If the graphical representation of the diffraction pattern is used to define the claim, then in the event of a litigation there will almost inevitably be contradictory views by the opposing expert witnesses on the comparison of the data for the allegedly infringing material with that claimed in the patent, including *inter alia* the preparation and handling of sample, methods and details of measurement, the work-up and presentation of data, *etc*. Similarly, for a selected list of 2θ values there will not always be a one-to-one correspondence between the number of peaks or the values they represent between the compared sets. Intensities (if given at all) may vary and the significance of differences in the precise values of the quoted peaks or lines in the XRPD pattern will be the subject of critique and debate.

A further point should be made here. We earlier made the distinction (see Section 7.5.4) between crystal-form purity and chemical purity. Here we note that there is a distinct and important difference between, on the one hand, the *polymorph identity* of a crystal form, *i.e.* the XRPD peaks that characterize that solid form, whether in isolation or in the presence of other solids and, on the other hand, the *polymorphic purity* of a particular sample, *i.e.* are there other solid forms of the same compound present and to what extent? A number of examples will serve to demonstrate some of the points raised here.

Fig. 7.5.6 shows the XRPD traces of the two polymorphic forms of ranitidine hydrochloride. This is an excellent demonstration of *polymorph identification* since the two major peaks in form 1 appear at 2θ values where there is a 'window' in form 2 and *vice versa*. Hence in a chemically pure sample of ranitidine hydrochloride there would be no difficulty in identifying which polymorph was present, or indeed if both were present.

In addressing the question of *polymorph purity*, the issue is whether a solid contains one form, and if not, how much of another particular form is present, either as the main component or as an 'impurity' of another solid form of the same compound. An example, wherein synchrotron XRPD achieved a limit of detection of 0.01 wt% of the minor component in salicylic acid–paracetamol mixtures (Gozzo, 2018), is given in Fig. 7.5.7

Chemists in general, and crystallographers in particular, are accustomed to comparing a list of peaks (in the current context XRPD peaks; in other cases IR, Raman or NMR peaks *etc*.) for the sample they are studying with those listed in the literature or in a patent. Rarely are all the peaks listed in a characterization. Rather, they are generally chosen by a person who is familiar with the material and the system of solids in which that material is

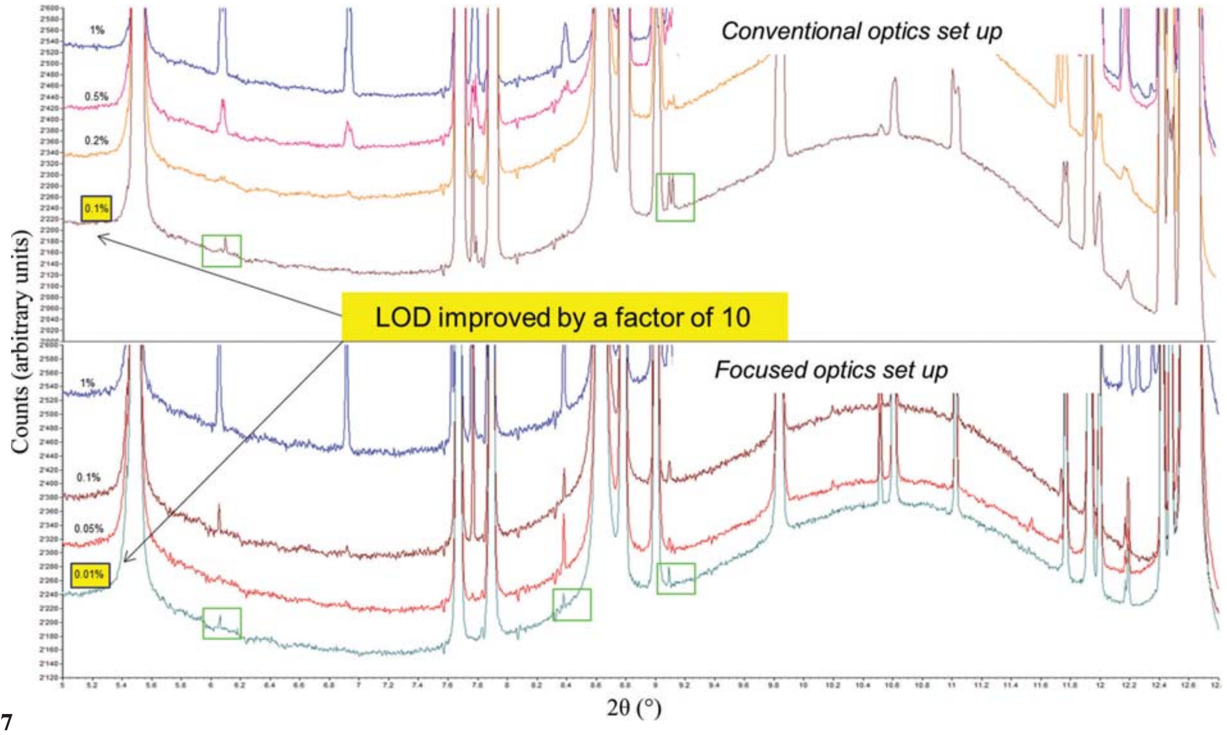

Figure 7.5.7
Synchrotron XRPD patterns of *ad hoc* mixtures of salicylic acid and paracetamol: the limit of detection of 0.1 wt% for the minor component achieved with a conventional optics setup was improved by a factor of 10 to 0.01 wt% with careful optimization of the beamline optics. From Gozzo (2018), with permission.

found, and represent what that person deems characteristic of that solid form. They need not be the most intense, but they generally represent what that person has come to recognize individually or collectively as representing that crystal form. For instance, in Fig. 7.5.6 one could easily imagine the choice of the two largest peaks in each of the traces as sufficient to define and distinguish between forms 1 and 2 of ranitidine hydrochloride, although certainly additional peaks might be added to the lists.

As noted above, when comparing experimentally determined peak positions with the published values, some peaks in the literature reference may not be present for the sample. The XRPD pattern of the sample will almost certainly contain many more peaks than the published list. Similarly, the comparison of two experimental XRPD traces will virtually never yield a perfect match. Peaks will not be in exactly the same position; some will be shifted slightly. The person carrying out the analysis will have to call upon experience with this kind of analytical reasoning as well as familiarity with the material in question in carrying out the comparison. This is often referred to as ‘fuzzy logic’, since it is not based on the digital yes/no or on/off logic of computers. However, it is a common reasoning process to practising chemists who routinely carry out such comparisons and analyses.

If the solid material is claimed using a list of peaks rather than an XRPD trace, then how many peaks should be included? Indeed, how many peaks are required to uniquely characterize a crystal form for a specific chemical entity? Should the claim(s) contain a maximum number of peaks, a minimum number of peaks, or is there some optimal number? Minimizing the number of peaks increases the risk that some other material (or even another crystal form of the same material) could have the same peaks (within experimental error), thus nullifying the novelty of the substance. On the other hand, defining the invented solid form in the claim by a large number of peaks may require finding all of them in allegedly infringing material, a task that becomes increasingly difficult as the number of peaks listed in the claim increases. This task is further complicated for *in situ* determination of infringing material at low concentrations and/or in the presence of excipients that may mask claimed peaks.

The patent literature reveals both extremes in the number of peaks claimed. An example at the minimalist end is the patent for one of the crystal forms of atorvastatin (Lipitor) (Briggs *et al.*, 2006), for which the first (independent) claim in the original patent in 1999 listed two peaks. The patent was re-examined in 2006 and the claim was reduced to one peak. On the other hand, a 2002 patent on a derivative of sildenafil (the active ingredient of Viagra) lists 99 peaks in the first – and only – claim (Harris *et al.*, 2006). The most intense peaks are not necessarily the most characteristic. Careful choice of the peaks included in the claim can make it difficult to challenge and can facilitate its enforcement.

The details of XRPD data vary widely in the patent literature. A survey conducted by Parker (2005) covering both the United States Patent and Trademark Office (USPTO) and the European Patent Office (EPO) for the period November 1988 – March 2005 is representative and illustrative of the situation. The numbers for the EPO (where relevant) are given in parentheses following those of the USPTO. The sample of 72 (27) patents chosen for review were selected from 42 for which ‘polymorphism’ appeared in the title, 100 reviewed of 3037 for which ‘crystalline’ appeared in the title, and 150 reviewed from 203 for which ‘crystalline’ and ‘drug’ appeared in the title. Twenty five (13) gave no data; 52 (21) recited XRPD characterization; the remainder cited another method or a combination of other methods. For those patents citing XRPD, 52 (16) contained numerical peak information, 9 (6) contained a figure with an XRPD trace, 12 (1) listed intensities, half of which were qualitative (*i.e.* s = strong, m = medium, w = weak, vw = very weak *etc.*), 6 (4) specify the radiation source and 1 (1) specifies the temperature and relative humidity. Twenty seven (5) of the patents listed ten peaks or fewer to define the crystal form, while 23 (11) designated ten or more peaks, and one designated 99 peaks. An additional datum of interest is the number of significant figures (SFs) associated with the numerical data: 25 (7) had peaks with one SF, 19 (5) with two SFs, 2 with 3 SFs, 3 (4) with four SFs and 1 with 5 SFs. The number of values listed varies from minimal to maximal. For instance, the first claim of US Patent 6,420,557 (Harris *et al.*, 2006) lists 99 peaks and intensities in the first (independent) claim for a specific crystal form, while the first (independent) claim of US Patent 5,969,156 (Briggs *et al.*, 2006) lists *either* of only two peaks as defining the invention. Current US case law suggests that the proof of literal infringement requires that most or all of the peaks listed *in a claim* be positively identified in the allegedly infringing material. This would seem to argue for including a minimum number of peaks in the claim, which again runs the risk of losing the novelty, since more than one material, or more specifically another solid form of the same material, may contain the same small number of peaks.

Since the claims define the invention, infringement must be proven by demonstrating that what is described in at least one of them has been copied. This case law was established in a case that also touches on a number of other aspects of the role played by powder diffraction in pharmaceuticals (Zenith Laboratories Inc., v. Bristol-Myers Squibb Co., 1994).

The antibiotic cefadroxil, marketed as a crystalline monohydrate claimed in US Patent No. 4,504,657 (the ’657 patent) issued in March 1985, is described in the patent in terms of its X-ray diffraction pattern, given as a list of 37 *d*-spacings and relative intensities in a table in the first claim with the leader ‘exhibiting essentially the following X-ray diffraction properties: . . . ’. The improvement of this substance over the earlier known material included greater stability and high bulk density, properties that enabled the production of smaller pills.

Prosecution of the ’657 patent was in fact quite lengthy, the original application dating from August 1979, and involved questions of similarities and differences in crystalline modifications.[1] The prior art included a 1973 patent (US Patent No. 3,781,282) (the ’282 patent) in which a modification of cefadroxil had also been prepared. This was termed the ‘Micetich form’ after one of the inventors. One of the questions surrounding the ’657 patent was whether the crystalline material described therein (known as the ‘Bouzard form’ or ‘Bouzard monohydrate’) was the same as or different from the ‘Micetich form’. In the end, the ’657 patent was granted, in essence recognizing the difference between the two.

In anticipation of the expiry of ’282 patent, there were attempts by generic pharmaceutical firms to make the Micetich form according to Example 19 in that patent in preparation for entering the market with the form that had gone off-patent. Those attempts invariably led to the Bouzard form, leading the companies involved to carry out experiments to claim *inherency* of the Bouzard form in the ’282 patent. Bristol-Myers’ (BM) explanation of these results included the role of unintentional seeding that tended to favour the formation of the Bouzard form rather than the Micetich form. A number of litigations ensued that involved these issues (*e.g.* Kalifarma, Inc. v. Bristol-Myers Company, 1989; Bristol-Myers v. United States International Trade Commission, 1989). In the former case, there was also a question of the identity of the various crystal modifications, determined mainly by powder X-ray diffraction, with conflicting opinions by various experts. There were many litigations and appeals. Many experiments were carried out and many issues arose in those cases. In the current context, the important point was that the X-ray powder pattern of the Bouzard form was indexed, showing that every line in the pattern could be accounted for by that crystal modification; this proved it was a unique and pure form.

The series of litigations continued over other issues, including the nature of crystal modifications (Zenith Laboratories, Inc. v Bristol-Myers Squibb Co., 1992, 1994). Zenith prepared and formulated a hemihydrate of cefadroxil, for which it submitted an abbreviated new drug application (ANDA) to the FDA. BM (now Bristol-Myers Squibb) contended that the FDA should require a much more extensive new drug application (NDA) for the hemihydrate, rather than approve it within the framework of the FDA monograph for the monohydrate. BM also alleged that the Zenith product converted to the monohydrate, thereby infringing the ’657 patent. BM’s theory of infringement was that the Zenith product converts to the Bouzard monohydrate after ingestion in the gullet and the stomach, as it is mixed with liquid. A US federal court found in favour of BM. Upon appeal, Zenith contended that the ’657 patent does not cover Bouzard-form crystals that might form momentarily in a patient’s stomach, and there were both legal and scientific grounds for the basis of that contention. One of the main points of contention was whether the XRPD pattern of the material found by BM in a patient’s stomach matched the claim of the Bouzard patent, as given in the table in Claim 1. Upon XRPD analysis following *in vivo* conversion, BM had identified 15 of the 37 diffraction lines cited in the claim. The court found that “Although the term ‘essentially’ recited in the claim permits some leeway in the exactness of the comparison with the specified 37 lines of the claim, it does not permit ignoring a substantial number of lines altogether”, and that “ . . . there was a failure of proof as to whether any crystals, assumed to form in the stomach from ingested cefadroxil . . . , literally infringe the ’657 claim”. On this basis, the appeals court reversed the lower court’s decision. One result of this decision is that many subsequent patent applications, including claims based on substances characterized by X-ray diffraction patterns and/or IR spectra, were framed in language that differs from that used in the ’657 patent; another result was that the claims (as opposed to the specifications) contain many fewer peaks, and only those that may be readily detected in the presence of other substances, such as excipients.

7.5.7.1. *Crystal habit*

As noted above, in the pharmaceutical industry XRPD may be employed in contexts other than solid-form identification or assessment of solid-form purity. One illustrative example dealt with the *crystal habit* of the widely used dipeptide artificial sweetener aspartame, marketed as Nutrisweet. In the original conventional manufacturing process, crystallization from aqueous solutions tended to produce needles with a diameter of 10 μm or less. The crystals were very fine, with large specific volume. These characteristics led to many problems in the filtration and drying processes, the formation of scale on reactor surfaces, and the high tendency to form a dust and hygroscopicity of the final product, which made it difficult to handle and unsuitable for use as a direct (*i.e.* table-top) sweetener (Kishimoto *et al.*, 1987; Ajinomoto Co., Inc., 1983).

Five crystal modifications of aspartame are known (Ajinomoto Co., Inc., 1983; Hatada *et al.*, 1985; Nagashima *et al.*, 1987; Tsuboi *et al.*, 1991; Kishimoto & Naruse, 1988; Furedi-Milhofer *et al.*, 1999). Many attempts were made to improve the quality of the

---

[1] See Kalifarma, Inc. v. Bristol-Myers Company (1989) for details of the history of the prosecution of the patent application.

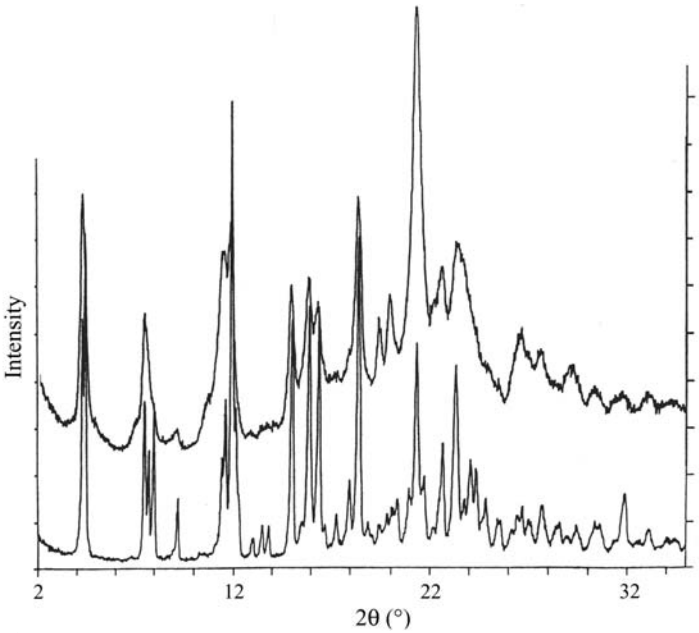

Figure 7.5.8
Comparison of the measured XRPD patterns for two different habits of aspartame. Upper, 'conventional' crystals; lower, 'bundle-like' crystals. [From Tarling (1991), with permission.]

crystals obtained from the conventional manufacturing process. The Japanese Ajinomoto Co. had a license to make aspartame and, as a result of 'intensive investigations to improve the workability (of the crystallization) step in the production . . . ', discovered that cooling aqueous solutions of aspartame without stirring led to 'bundle-like' aggregates of crystals (Kishimoto & Naruse, 1987). These crystals had significantly improved handling characteristics compared to the conventional crystals. This process was subsequently refined and led to an Ajinomoto European patent, granted in 1985.

In April 1992, the Opposition Division of the European Patent Office concluded that the bundle-like crystals were the same as the conventional crystals. In response to that decision, Ajinomoto presented a detailed study of the differences between the two (Tarling, 1992). The two types of crystals were *different habits* rather than polymorphs. The bundle-like crystals, produced without stirring, had a higher degree of crystal perfection than the conventional crystals produced with agitated stirring. The Tarling report identified some 'significant and reproducible differences' in a number of properties determined with a variety of analytical techniques. The differences formed the basis of the Ajinomoto response to the opposition, and included reproducible differences in the following properties: specific volumes, rate of dissolution, water content, density, solid-state NMR spectra, polarizing light spectroscopy and X-ray powder diffraction, as shown in Fig. 7.5.8.

For the latter, there are some slight differences in the peak positions, which was attributed to differences in water content and degree of internal crystal strain. There are some more obvious differences in relative intensities, including the position of the strongest peak. There are clear differences in the peak widths, which also reflect differences in the nature of the crystalline material obtained by the two methods; scanning electron microscopy, single-crystal X-ray diffraction (Hatada *et al.*, 1985; Kishimoto *et al.*, 1989) and crystal-habit modelling were used to determine the preferred orientation and to simulate the X-ray powder patterns of both forms to show a good comparison with the experimental data.

In May 1997, the Boards of Appeal of the European Patent Office set aside the 1992 opposition to the Ajinomoto patent (European Patent Office, 1997), and a New European Patent Specification was issued (Ajinomoto Co., Inc, 1998).

The ultimate value of a patent is judged by how well it can be defended against potential challengers and infringers. One important component of that process is how well the invention is defined, and XRPD can be the essential technique in defining the invention. If XRPD is the basis for defining and characterizing the invention, then determining a match between the invention and alleged infringing material is essential in that defence. We have noted above some of the pitfalls and difficulties in comparing a 'defining' XRPD pattern with that from an experimental sample. Increasingly sophisticated methods are being developed to make that comparison less subject to human judgement and more algorithm-based. While such developments are to be encouraged, there is a danger lurking in assigning a single number to a comparison of two sets of data, as courts naturally would like to do. Nevertheless, a great deal can be said for the ability of human beings to compare and recognize patterns, even in seemingly complex situations, and these judgements should remain an integral part of the intellectual property scene.

7.5.8. Counterfeit medicines

Counterfeit medicines are a global threat to public health. The US Food and Drug Administration (FDA, 2012) describes the situation.

> Counterfeit medicine is fake medicine. It may be contaminated or contain the wrong or no active ingredient. They could have the right active ingredient but at the wrong dose. Counterfeit drugs are illegal and may be harmful to your health. FDA takes all reports of suspect counterfeits seriously and, in order to combat counterfeit medicines, is working with other agencies and the private sector to help protect the nation's drug supply from the threat of counterfeits.

In order to give some direction to aid the prevention of counterfeiting of drugs, the FDA have published guidance for industry on (I) *Standards for Securing the Drug Supply Chain – Standardized Numerical Identification for Prescription Drug Packages*, (II) *Incorporation of Physical–Chemical Identifiers into Solid Oral Dosage Form Drug Product Anticounterfeiting*, and (III) *Drug Supply Chain Security Act Implementation: Identification of Suspect Product and Notification*, see https://www.fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/default.htm. In (II) the FDA pointed out that, for example, adding a physical–chemical identifier (PCID) to a nonfunctional tablet film coating is covered by this guidance, but adding a non-functional film coating that contains a PCID to a previously uncoated tablet involves manufacturing changes that are not covered by this guidance. Also the incorporation of a PCID into the packaging or labelling is not covered in this guidance. In addition, this guidance does not apply to manufacturing or formulation changes, made in conjunction with the addition of a PCID, that go beyond simply inserting the PCID into a blending or mixing operation. With that, the addition of a marker that can be used to identify counterfeit medicines, using for example spectroscopic or X-ray methods, is not a simple task.

Several incidents have proven that the US has a serious and growing problem with counterfeit medicines. In 2012, forged steroids killed 11 people and made another 100 sick (*The Economist*, 2012). In another example, vials puportedly of the cancer drug Avastin were shown not to contain the API. And in 2007–2008, 149 patients died from a contaminated batch of the blood thinner Heparin (*The Economist*, 2012). These cases and others have shown that powerful tools are required to identify counterfeit medicines reliably without adding special markers, as pointed out by the FDA guideline described above. Earlier we established that XRPD is a key analytical tool in the pharmaceutical industry. With powerful developments such as ultrafast detectors, Beckers (2008) has shown that laboratory-based XRPD equipment can be used to detect counterfeit tablets in intact blisters. Beckers reported studying commercially available tablets from European pharmacies and specially produced tablets for testing purposes. All tablets were contained within blister packs within a polymer cavity and aluminium lidding. XRPD measurements were performed with a diffractometer equipped with a focusing mirror and motorized high-throughput stage. The blister cards were mounted on a metal frame and the diffraction signals were measured in transmission mode. In other words, the measurement is non-invasive and non-destructive. But the escalating issue of counterfeit medicines demands new measures, including rapid and non-destructive analytical tools that are easy to use in the field by non-experts. Newly developed X-ray-based tools are among those which can be used in the field. Taylor (2009) has shown that portable X-ray diffractometers can be used to rapidly identify genuine and fake pharmaceuticals. The key is to equip the X-ray system with the correct X-ray pattern database for identifying pharmaceutical products. The instrument requires around 15 mg of loose powder to perform an analysis. This means that a tablet needs to be rendered into a powder for sample preparation, so such a measurement is destructive, a distinct disadvantage. The instrument does not contain any moving parts or variable parameters and requires about 2 to 3 minutes of acquisition time. The resulting diffraction pattern is then ready for processing with the software included. Other promising potential tools that can be used for identifying counterfeit medicines in the field are portable near-infrared and Raman spectrometers (O'Neil, 2012) and nano-encoding of individual tablets or pills (NanoGuardian, 2012).

Counterfeit medicines clearly also pose a serious threat to intellectual property (WHO, 2006; Fernandez *et al.*, 2008). Forged pharmaceutical products are not subject to regulatory supervision and, as noted above, at a minimum often lack therapeutic value or, much worse, may in fact threaten the health of the unwary or uninformed consumer. Thus, health officials as well as the holders of patent rights on drugs are on the watch for counterfeit pharmaceutical products. This is very much a cat-and-mouse game with the regulators and industrial watchdogs constantly improving methods of detection, while the counterfeiters attempt to match and outdo their sleuthing techniques with ever more sophisticated methods of copying. XRPD is an important part of the armoury on this economic and scientific battleground and is being used extensively in the efforts to detect forged products and prosecute the counterfeiters (Maurin *et al.*, 2007). A typical example is given in Fig. 7.5.9.

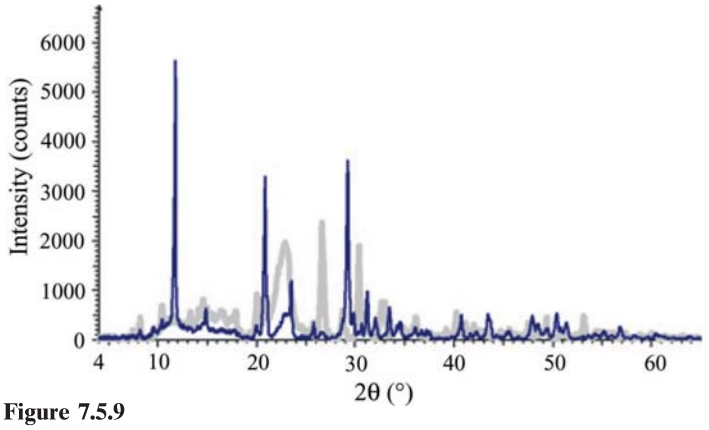

Figure 7.5.9
The comparison of diffraction patterns of a counterfeit 'Viagra' tablet and the original drug (shown as the thick lines in grey) taken with the coatings removed [from Maurin *et al.* (2007) with permission from Elsevier].

In this regard, it is worth pointing out that the limits of *in situ* detection for very low concentrations of a solid form or for 'polymorphic impurities' are constantly being extended. Yamada *et al.* (2011) have demonstrated the ability to detect crystalline substances in intact pharmaceutical tablets to a limit of quantification of 0.05% and a limit of detection of 0.02% using synchrotron powder diffractometry. A recent patent application claims the ability to detect a 'non-prevailing polymorph' (*i.e.* a polymorph impurity at a low concentration) at a concentration of 'even less than 0.005% by weight' (Brescello *et al.*, 2016; see also Cotarca, 2012).

7.5.9. Concluding remarks

XRPD plays a central role in virtually every aspect of research, development, production and market protection in the pharmaceutical industry. Some of the uses of XRPD, such as quality control, may be considered routine, but those are the measurements that determine whether a solid material passes inspection for purity or not. Considerable investment goes into each batch of API, but in addition to the financial consequences of a failed batch – or a failure to recognize a failed batch – the health of many people rests on robust and reliable test methods. In spite of the routine nature of some of the applications of XRPD in the pharmaceutical industry, there are constant demands to increase the sensitivity and selectivity of the analytical methods, prompting the development of cutting-edge and sophisticated technology. Indeed, many of the new initial practical applications of new technology in XRPD are to pharmaceutical problems, confirming the long-term symbiotic relationship between pure science and practical application in virtually every aspect of the pharmaceutical industry. Indeed, with industry increasingly relying on XRPD not only to aid in research and development, but also to establish and protect intellectual property rights and the pharmaceutical integrity of its products worldwide, it is certain that the role of XRPD in the pharmaceutical industry will continue to grow and expand.

7.6. Selected applications of Rietveld analysis in the aluminium industry

F. R. Feret

7.6.1. Introduction

The Rietveld method has been used increasingly in the aluminium industry since the beginning of the 1990s. The initial applications were predominantly for the analysis of raw materials and selected products. During the intervening decades, its use has expanded to every stage of aluminium production and Rietveld analysis has now become a recognized analytical technique, applied routinely in bauxite exploration, reduction and fabrication processes. Typical applications of the Rietveld method in the aluminium industry at present are listed in Table 7.6.1. The number of crystalline phases determined summarizes usual industrial experience, and may vary among laboratories. The success rate of the method (understood as the accuracy and reliability of the information obtained) obviously depends on the matrix. The Rietveld method has replaced existing methodology in plant laboratories as a primary and universal method for the determination of the phase composition of electrolytic bath. Freeing the plant laboratory from older calibration-curve-based methods improves the reliability and accuracy of all determinations of mineralogical phase concentrations.

The conventional cavity-slide sample-preparation technique is the most commonly used for the application of the Rietveld method; however, briquetting dominates in the analysis of electrolytic bath. Cavity-slide sample preparation is a standard X-ray diffraction technique, which allows presentation of material for the analysis in the instrument. The finely ground sample material is packed into a cavity in a support (called a slide) in such a way that the sample material remains flat. Materials such as the electrolytic bath that do not have self-binding properties require addition of a binder prior to grinding. Briquetting involves use of a press (mostly hydraulic) to compress sample material into a mechanically stable briquette. In some plants, highly sophisticated automatic systems handle grinding and briquetting of a few hundred samples a day.

Rietveld analysis has not only replaced traditional X-ray diffraction calibration methods; it has also opened the door for new applications that were not previously possible. The use of the Rietveld method to characterize selected materials unique to the aluminium industry (for example bauxite, red mud, alumina, electrolytic bath, spent potlining and dross) has became routine. PANalytical's *X'Pert High Score Plus* software was used in the studies detailed here.

Table 7.6.1
Typical applications of the Rietveld method in the aluminium industry

Material	No. of phases	Sample type	Success rate
Bauxite	14–24	Cavity slide	Limited
Red mud	30–60	Cavity slide	Limited
Alumina	8	Cavity slide	Limited–high
Electrolytic bath	9–16	Briquette, cavity	High
Spent potlining	30–60	Cavity slide	Limited–high
Dross	10–20	Cavity slide	High
Intermetallics	> 20	Cavity slide	High

7.6.2. Bauxite

Aluminium-bearing minerals constitute a group of raw materials vital to the aluminium industry. Bauxite, a mixture of hydrated aluminium minerals, is the primary raw material used in the Bayer process (Habashi, 2005). Other materials of concern, such as clay, red mud and sand, are waste products. Clay is obtained during bauxite washing, whereas red mud and sand appear during the bauxite digestion process.

An accurate estimate of the quality of the bauxite that is being surveyed, mined and supplied is important to the efficient operation of a mine and a Bayer plant. Traditional methods used to determine bauxite phase composition are based on wet chemistry (WCh). They are relatively slow and require large supplies of chemicals as well as considerable space and manpower. Compared to wet chemistry, powder X-ray diffraction (PXRD) offers speed and a much lower cost of analysis, but is very often less accurate. Conventional tube-based X-ray diffraction is known to be seriously affected by the sample's amorphous content (Figs. 7.6.1 and 7.6.2). In the analysis of Fig.

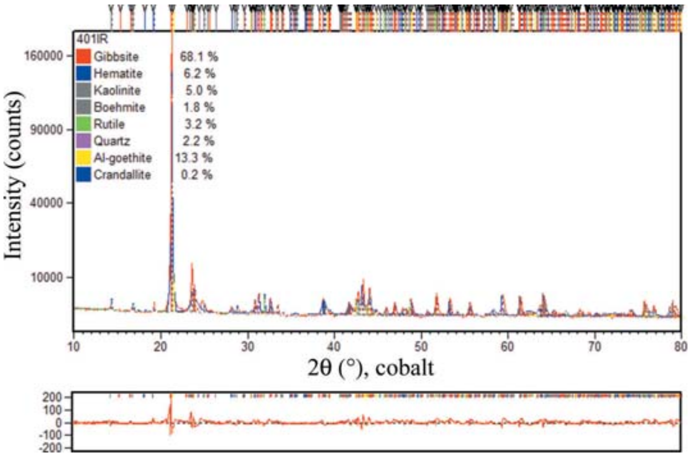

Figure 7.6.1
Example 1 of Rietveld refinement for bauxite.

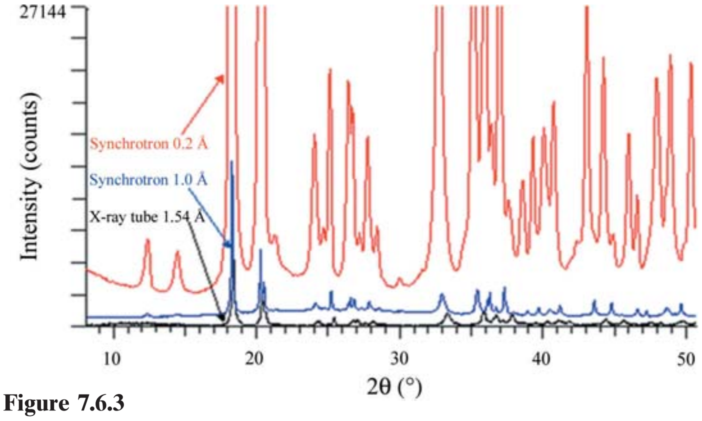

Figure 7.6.3
Comparison of diffractograms of BXT-12 from three sources. Red: synchrotron radiation, 0.2 Å; blue: synchrotron radiation, 1 Å; black: Cu *Kα* X-ray tube, 1.54 Å.

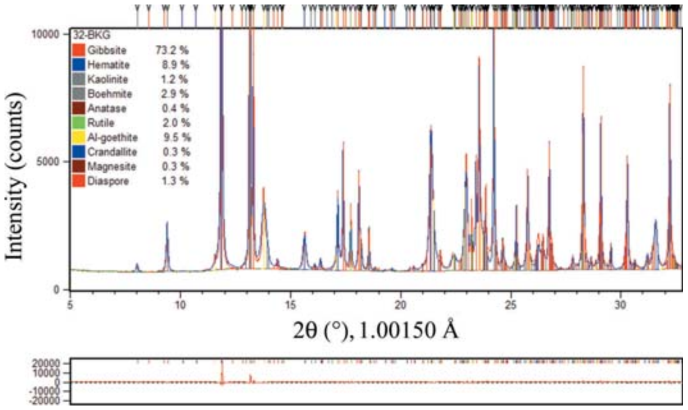

Figure 7.6.5
Rietveld refinement for BXT-02.

7.6.1, gibbsite is underestimated by approximately 8% and in Fig. 7.6.2 it is overestimated by the same amount with respect to WCh and mass-balance calculations. As a result of the low X-ray power, the limit of detection (LOD) of phase constituents is relatively high (Ni & Khalyapina, 1978). Not many studies of the application of Rietveld analysis to bauxite have been published (Bennett *et al.*, 1999). It was believed that synchrotron-radiation diffraction patterns with much better signal-to-noise ratios would help provide new information that cannot be obtained with X-ray tube instrumentation (Feret & See, 2010). It was also hoped that the diffractograms would facilitate detection of the amorphous content, which seriously plagues analysis of bauxite and red-mud material using conventional XRD.

The samples for the synchrotron experiments were ground to <325 mesh and packed into a thin-wall glass capillary (Feret & See, 2010). Diffractograms were recorded at the Japan Synchrotron Radiation Research Institute (JASRI) at wavelengths of 1.002 and 0.202 Å and covered 5–75° and 0–15° 2*θ*, respectively. The effect of the power of synchrotron radiation on a bauxite diffractogram can be appreciated in Fig. 7.6.3, which compares diffractograms of BXT-12 (Rio Tinto Alcan bauxite standard) from the 1 and 0.2 Å synchrotron and 1.54 Å Cu *Kα* radiation sources. The synchrotron diffractograms are not only much more intense, but the peak/background ratio and resolution are much higher than in the laboratory pattern. The 0.2 Å source diffractogram simply dwarfs the two other diffractograms by a large margin. All three features facilitate quantitative phase analysis. The first two peaks from kaolinite and boehmite are very well defined on the 0.2 Å source diffractogram.

In order to characterize all bauxite samples involved in the project, wet chemistry, BQuant (Kimmerle *et al.*, 1997), XDB Hungalu (Sajó, 1994), X-ray fluorescence (XRF) spectroscopy (Feret, 1993) and thermogravimetric analysis (TGA) determinations were carried out, in addition to Rietveld investigations.

Quantitative Rietveld results for Rio Tinto Alcan (RTA) bauxite reference materials using the 0.2 and 1 Å source diffractograms are presented in Figs. 7.6.4 and 7.6.5, respectively. In Table 7.6.2, major phase concentrations obtained for BXT-12 are compared. Gibbsite is to some extent overestimated and the boehmite concentration is underestimated using synchrotron radiation and the X-ray tube diffractograms. The boehmite concentration is lower from the 0.2 Å source diffractogram than from other sources. In contrast, Al-goethite (at 3.2%) is clearly confirmed in BXT-12 bauxite, while it is underestimated using the laboratory data. Anatase in Table 7.6.2 represents the sum of anatase and rutile.

Figs. 7.6.5 and 7.6.6 illustrate Rietveld results for BXT-02 and BXT-08, and confirm diaspore and ilmenite, respectively; these are impossible to quantify at these low levels using an X-ray tube diffractogram.

Apart from the phases appearing in Figs. 7.6.4–7.6.6, additional phases such as calcite, dolomite, magnetite, magnesite, chamosite, illite, muscovite, hausmanite, manganite, chabazite and others may also appear in small quantities, depending on the bauxite deposit.

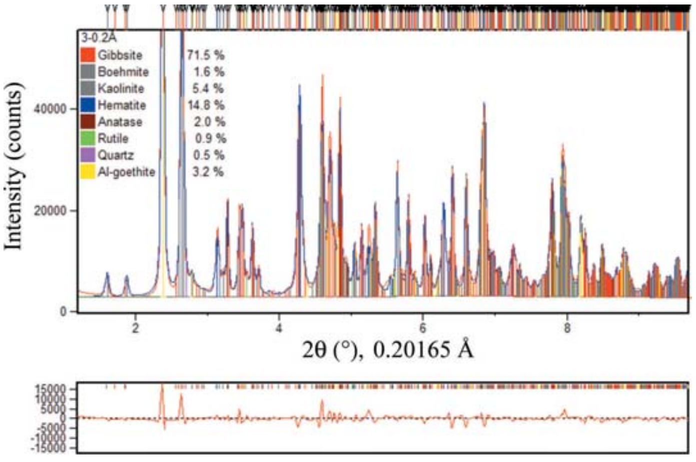

Figure 7.6.4
Rietveld refinement for BXT-12.

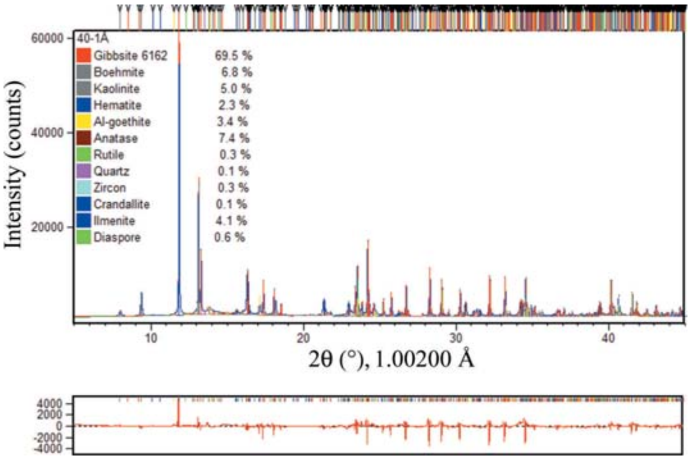

Figure 7.6.6
Rietveld refinement for BXT-08.

Table 7.6.2
Comparison of phase concentrations (wt%) for BXT-12

	Gibbsite	Boehmite	Kaolinite	Goethite	Haematite	Anatase	Quartz
Wet chemistry	69.5	3.0	5.9				
Mass balance	68.7	3.2	6.9	3.0	13.5	3.2	0.3
Rietveld (synchrotron radiation, 0.2 Å)	71.5	1.6	5.4	3.2	14.8	2.9	0.5
Rietveld (Cu X-ray tube)	71.2	2.4	5.9	1.2	15.7	3.2	0.4

When using an X-ray tube as the source, the concentrations of gibbsite are mostly overestimated by the Rietveld method (sometimes largely) with respect to WCh concentrations (Fig. 7.6.7). Most of the time, the main reason is underestimated boehmite, kaolinite and goethite concentrations. Because the Rietveld analysis normalizes the sum of all concentrations to 100%, increasing the content of the major constituent (gibbsite) compensates for the missing amorphous content. The correlation curve also demonstrates that the synchrotron diffractograms and XDB interpretations help to obtain the best correlation with WCh.

The Rietveld method using X-ray tube diffractograms tends to strongly underestimate kaolinite. This is evident from the XRF − WCh mass balance. The underestimation convincingly suggests that X-ray amorphous aluminosilicate must be present. In contrast to X-ray tube data, synchrotron data are much less affected by the amorphous content. The WCh and BQuant correlation for kaolinitic SiO_2 appears to be good, but this determination was modelled using Rio Tinto Alcan standards in which the total SiO_2 is relatively low. The XDB mass-balance calculations of the %SiO_2 in kaolinite,

$$\text{kaolinitic}\,SiO_2\,(\text{XDB}) = (\%SiO_2 - \%\text{quartz}),$$

provide the best fit with the WCh data.

The synchrotron study helped to validate the analytical methods employed for bauxite phase quantification and has changed our understanding of the bauxite matrix. Kaolinite and goethite, in particular, were already believed to be partially amorphous. However, contrary to past beliefs, even gibbsite and haematite may appear partially amorphous. The problem of bauxite amorphous content, although anticipated, was shown to have a profound effect on the quantification of selected phases using Rietveld and XDB methods and X-ray tube diffractograms. Simply, if a part of the bauxite matrix is X-ray amorphous, it will not contribute fully to a diffractogram. If several mineral contributions are missing on a diffractogram simultaneously, they can be quantified as a group, but not individually. The bauxite amorphous content, believed to be at the level of a few per cent, appears to be much higher than that.

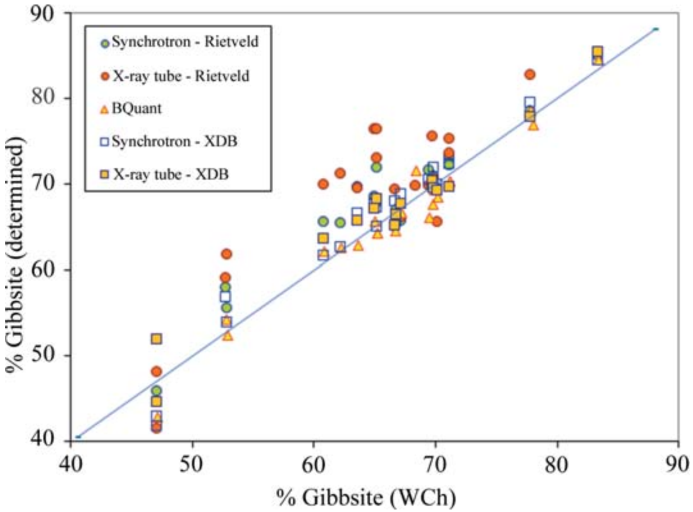

Figure 7.6.7
Comparison of gibbsite concentrations determined by different methods. %Gibbsite determined by various methods is compared with %gibbsite obtained from WCh analysis. The methods used are: synchrotron sample measurement with Rietveld-XRD interpretation; X-ray tube sample measurement with Rietveld-XRD interpretation; BQuant software, which uses XRF elemental composition and loss-of-mass data; synchrotron sample measurement with interpretation using XDB software; and X-ray tube sample measurement with interpretation using XDB software.

Despite high expectations, the synchrotron data did not allow phase concentrations equivalent to wet chemistry or mass-balance calculations to be obtained for several bauxites. Although powerful, synchrotron radiation by itself does not permit accurate quantification of amorphous phases. One of the methods described by Madsen & Scarlett (2008) must be used. On the other hand, synchrotron data, especially from the 0.2 Å source, resulted in a more detailed study on bauxite than conventional XRD.

7.6.3. Quantification of quartz in bauxite

Quartz is one of the important phase constituents of any bauxite and may vary from a small fraction to over 60% of the total SiO_2 concentration. At present, the most practical method of estimating quartz is by wet chemistry or using conventional XRD methods. Whether employing a direct or Rietveld approach, the XRD method is difficult, and not possible for small quartz concentrations because of severe line overlaps.

A new method devised for quantification of quartz in bauxite uses material calcined at 1273 K (Feret & Roy, 2002). This is an example of converting a difficult problem into one more easily solved by physical treatment. Major bauxite hydrated phases, such as gibbsite, boehmite, kaolinite and goethite, are entirely decomposed in the calcination process. The calcination proce-

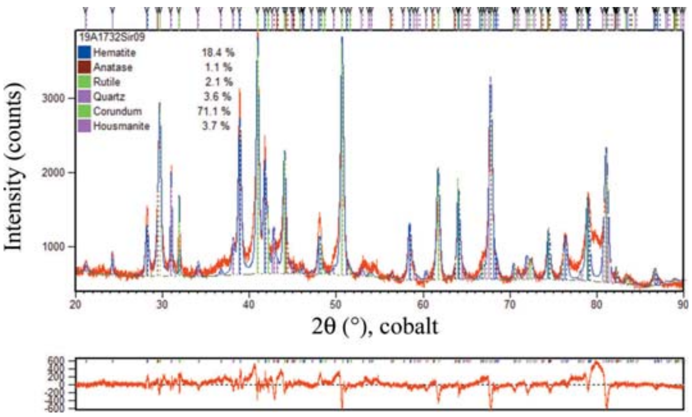

Figure 7.6.8
Rietveld quantification of calcined bauxite.

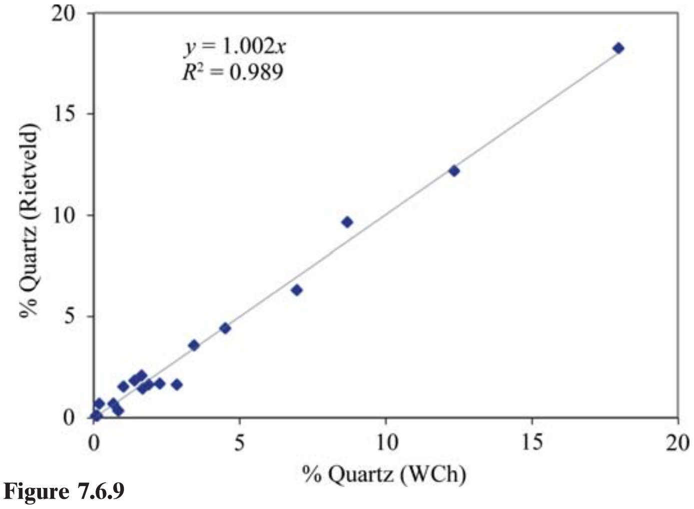

Figure 7.6.9
Comparison of % quartz determined by WCh and Rietveld methods.

dure converts kaolinite (the principal SiO_2 carrier) into amorphous material. In addition to the amorphous portion, there are just four major crystalline phases present in the calcined material: corundum, quartz, rutile and haematite (Fig. 7.6.8). Depending on the origin of the bauxite, some secondary phases (for example hausmanite, Mn_3O_4) can also occur. Corundum crystallizes from the decomposition products of major Al-bearing hydrates, mostly gibbsite and boehmite. Quartz in the calcined bauxite corresponds to the primary quartz occurring in the initial sample. Anatase is readily converted by heat into the more stable rutile at temperatures as low as 673 K. The amount of rutile in the calcined sample is the sum of the primary rutile and that resulting from anatase transformation. Rutile is employed as the internal standard. The haematite present is the sum of the primary haematite and haematite formed by goethite decomposition.

In order to determine the absolute quartz concentration, the quartz content from Rietveld analysis, quartz (R), needs to be corrected for various dilution effects in one single step, using the rutile as an internal standard. Employing one simple correction equation, the corrected quartz concentration, %quartz, is

$$\%\mathrm{quartz} = \mathrm{quartz}\ (\mathrm{R}) \frac{\mathrm{t.TiO_2}}{\mathrm{rutile}\ (\mathrm{R})}, \tag{7.6.1}$$

where $t.TiO_2$ is the total TiO_2 known from XRF, and rutile (R) is the rutile content from the Rietveld estimate. All of the Ti detected by bulk analysis is present as rutile. The accuracy of the quartz determination with the new method corresponds to that obtained by the conventional 'by difference' approach (Fig. 7.6.9). This approach is based on the total SiO_2 determined by XRF and kaolinitic silica (Si150) determined by WCh. The study also proves that SiO_2 determined in the low-temperature digestion process (Si150) is due to kaolinite and illite and not just due to kaolinite, as was previously believed. This fact has important implications for the plant processing of bauxite that contains illite.

7.6.4. Occurrence and characterization of Zn and Mn in bauxite

Zinc is one of the secondary elements occurring in Caribbean bauxite and the associated non-bauxitic material. It is generally believed that Zn in bauxite can either occur in gahnite ($ZnAl_2O_4$) or sphalerite (ZnS), or substitute for Fe in goethite. Manganese represents an appreciable impurity in Caribbean bauxites and is identified in diffractograms as lithiophorite $(Li,Al)MnO_2(OH)_2$. As Zn has been observed to increase with the MnO content, the objective of this study was to understand better the mineralogical nature of the Zn and Mn compounds. Data from 340 bauxite samples of different origins were assembled (Feret & See, 2006). It was found that Zn in bauxite could not possibly substitute for Fe in goethite or haematite (Fig. 7.6.10). Strong evidence was obtained that Zn occurs in the same compound as Mn. Application of the Rietveld method to characterize diffractograms and other XRD data suggest an aggregate, which we may call 'zincophorite' $Al(Zn_xMn_{1-x})O_2(OH)_2$. The x parameter could vary from 0.02 to 0.24. The concentration data corresponding to the group of samples investigated are given in Fig. 7.6.11.

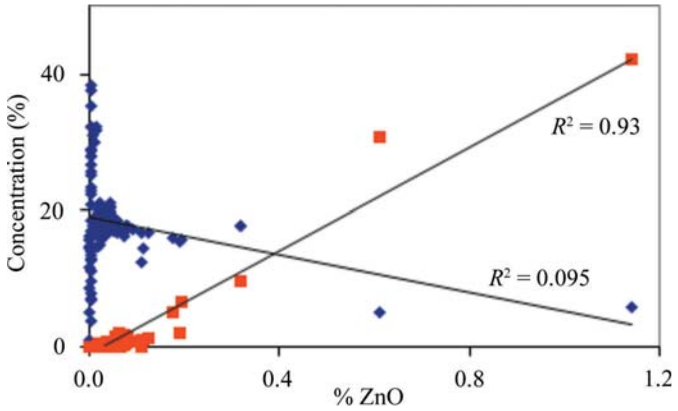

Figure 7.6.10
Correlation of ZnO *versus* MnO and Fe_2O_3 in bauxite. Red points represent MnO, blue points represent Fe_2O_3.

In Fig. 7.6.11, concentrations of ZnO are plotted against the concentrations of MnO and zincophorite. The correlation between the ZnO and MnO content is strong. Some points representative of zincophorite occur much below those of MnO at high ZnO concentrations. This is highly suggestive that a portion of lithiophorite might be amorphous.

7.6.5. Red mud (bauxite residue)

Red mud is the (semi-)solid waste product from the initial digestion of bauxite in caustic in the Bayer process. Storage, remediation and disposal of red mud represent significant challenges to a Bayer plant. The red colour arises from iron-containing compounds in the bauxite. Red muds consists of complex assemblages of minerals, and their analysis is a challenge.

Certain red-mud samples were analysed with synchrotron experiments (Feret & See, 2011). A dedicated control file containing all necessary crystallographic parameters was devel-

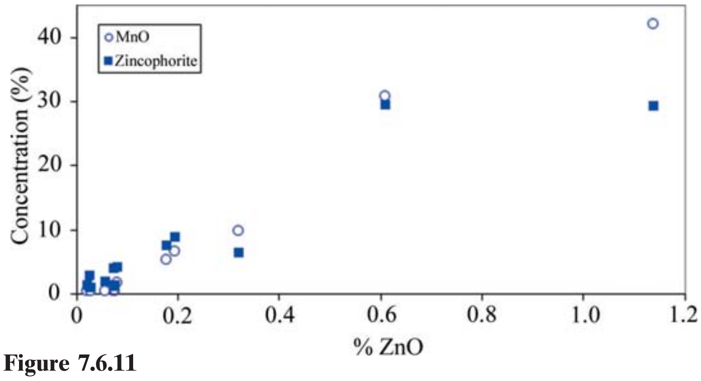

Figure 7.6.11

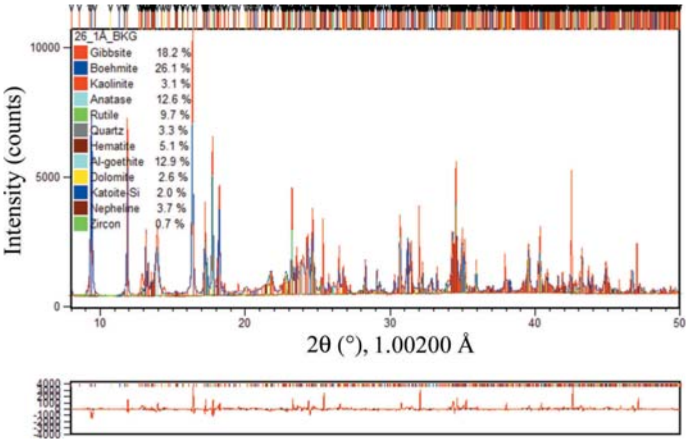

Figure 7.6.13
Example 2 of Rietveld refinement for red mud.

oped for quantification of 45 mineralogical phases in red mud. The maximum number of crystalline phases allowed during Rietveld refinement is limited in most commercial programs. Hence, the refinement was a tedious and time-consuming process beginning with phase confirmation and rejection, followed by Rietveld trials for a selected group of minerals. If a particular mineral was confirmed to be absent during the trial, it was replaced by another mineral. Given the large number of potential choices, most minerals determined with a concentration below 0.5% were rejected as unreliable. Concentrations of 28 different mineralogical phases in the red-mud matrix were determined: gibbsite, bayerite, boehmite, kaolinite, anatase, rutile, quartz, haematite, Al-goethite, sodalite, carnegieite, calcite, katoite-Si, brookite, ilmenite, portlandite, nepheline, perovskite, cancrinite-H_2O, cancrinite-CO_3, cancrinite-NO_3, cancrisilite, carbonate-hydroxyl-apatite, zircon, nosean, diaspore, lawsonite and schaeferite.

The phase-identification process followed by Rietveld refinement involved four different Al–Na silicates: sodalite ($Na_{8.08}Al_6Si_6O_{28.88}S_{0.98}$), cancrinite ($Na_{7.14}Al_6Si_6O_{31.6}$), cancrinite-$NO_3$ ($Na_{7.92}Al_6Si_6O_{31.56}N_{1.74}$) and nosean ($Na_8Al_6Si_6O_{28}S$).

The concentrations in Figs. 7.6.12 and 7.6.13 were reported by the Rietveld program and are overestimated owing to the X-ray amorphous portion of the sample material. In order to express the content of the crystalline phases more realistically, the sample amorphous content needed to be determined first.

Red mud is known to be partially amorphous. Selected phases such as haematite, quartz, rutile and anatase are considered to be crystalline in the red-mud matrix. However, phases such as sodalite or cancrinite account for only some of the aluminosilicates. Hence, one of the objectives of the study was to verify whether synchrotron radiation could characterize and quantify the amorphous phase(s). Initial Rietveld concentrations of the

Table 7.6.3
Summary of the phase composition of red mud

Mineral	Chemical formula	Maximum (%)	Minimum (%)
Gibbsite	$Al(OH)_3$	24.4	0.7
Bayerite	$Al(OH)_3$	4.0	3.6
Boehmite	$AlO(OH)$	41.3	3.6
Kaolinite	$Al_2Si_2O_5(OH)_4$	4.7	2.2
Anatase	TiO_2	13.5	2.5
Rutile	TiO_2	10.3	0.6
Quartz	SiO_2	4.9	0.2
Haematite	Fe_2O_3	66.2	0.6
Al-goethite	$(Fe,Al)_2O_3{\cdot}nH_2O$	57.5	1.7
Sodalite	$Na_{8.08}Al_6Si_6H_{1.92}O_{28.88}S_{0.98}$	22.5	1.8
Carnegieite	$Si_4Al_4Na_4O_{16}$	2.5	1.3
Calcite	$CaCO_3$	35.0	1.0
Dolomite	$CaMg(CO_3)_2$	2.5	1.5
Katoite-Si	$Ca_3Al_2(SiO_4,CO_3,OH)_3$	8.3	2.3
Brookite	TiO_2	5.4	3.1
Ilmenite	$FeTiO_3$	6.9	6.9
Portlandite	$Ca(OH)_2$	2.9	1.4
Nepheline	$NaAlSiO_4$	2.0	0.4
Perovskite	$CaTiO_3$	9.5	1.5
Cancrinite-H_2O	$Na_8(Al,Si)_{12}O_{24}(OH)_2{\cdot}2H_2O$	38.8	3.8
Cancrinite-CO_3	$(Na,Ca)_8(Al,Si)_{12}O_{24}(CO_3){\cdot}4H_2O$	9.1	8.6
Cancrinite-NO_3	$Na_{7.92}Si_6Al_6O_{31.56}N_{1.74}$	42.8	0.6
Cancrisilite-CO_3	$Na_{7.86}(AlSiO_4)_6(CO_3)(H_2O)_{3.3}$	4.6	4.6

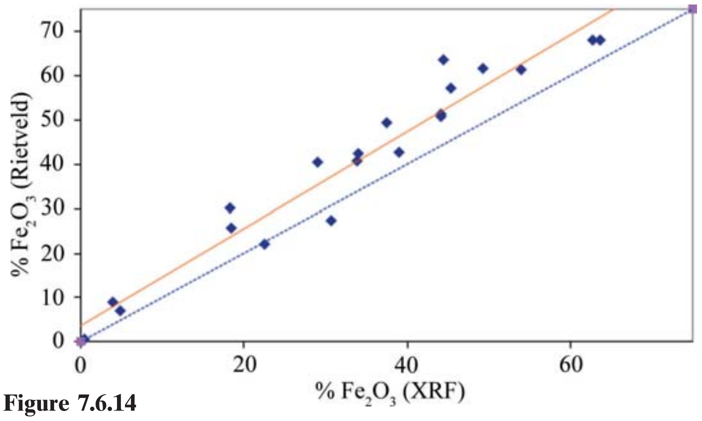

Figure 7.6.14
Correlation between XRF and Rietveld data for Fe_2O_3. The red solid line depicts the experimental correlation for %Fe_2O_3 as obtained by XRF and calculated from haematite and Al-goethite (Rietveld determined phases). The blue dotted line marks the theoretical correlation (45°).

crystalline phases allowed calculation of concentrations for major element oxides: Fe_2O_3, CaO and TiO_2. Then, estimation of the sample amorphous content was made using concentrations obtained from Rietveld estimated phases and determined by bulk XRF analysis. For some samples, the corresponding mass balances between XRF and Rietveld data suggest the occurrence of a significant quantity of amorphous material. Fig. 7.6.14 illustrates a correlation between XRF and Rietveld data for Fe_2O_3. The Fe_2O_3 concentrations from Rietveld analysis are clearly overestimated.

In red-mud samples, the average amount of the amorphous content was 18% and the maximum was 33%. With increasing amorphous content, the mass-balance deficit for Na, Al, Si and H_2O also increases. This indicates that a hydrated sodium aluminium silicate (resembling sodalite) makes up most of the amorphous content. Moreover, red mud is very complex in terms of the number and type of residual and/or neo-formed possible crystallographic phases that might occur. The cycles of phase identification, Rietveld phase quantification and mass-balance calculations were carried out for all samples several times. Mass-balance calculations provided feedback, triggering the beginning of a new cycle. In Table 7.6.3, a summary of the phase-composition range is given.

In spite of the time and effort put into the evaluation stage, the study clearly indicates that using high-quality synchrotron diffractograms is not enough to characterize the sample X-ray-amorphous content completely, and the true sample composition is not known. Differences among mass-balance estimates of the amorphous content for individual samples reflect the limited accuracy of the method.

7.6.6. Alumina

With red mud, the Bayer process produces a basic sodium aluminate solution, from which aluminium hydroxide is crystallized. The $Al(OH)_3$ is then calcined. Depending on the degree of calcination, metallurgical or ceramic grade aluminas are obtained. They differ with respect to the α-alumina content, by virtue of grindability, particle shape and size, impurity content, and other properties.

Application of PXRD in the analysis of alumina in the aluminium industry dates back to the 1960s. Special aluminas (non-metallurgical grades) have always presented a major challenge (Feret, 2000, 2012). Aluminas may have a variety of morphological forms (see Fig. 7.6.15) for which there are marked differences in relative intensities of their major XRD reflections (the preferred-orientation effect), as shown in Fig. 7.6.16. Comparing intensities (whether peak height or integrated) of selected reflections from a sample with those of a reference material may cause a serious analytical error. If the intensity of a selected reflection is compared to that from a reference standard for quantification, then the morphology of this standard must be the same as the unknowns.

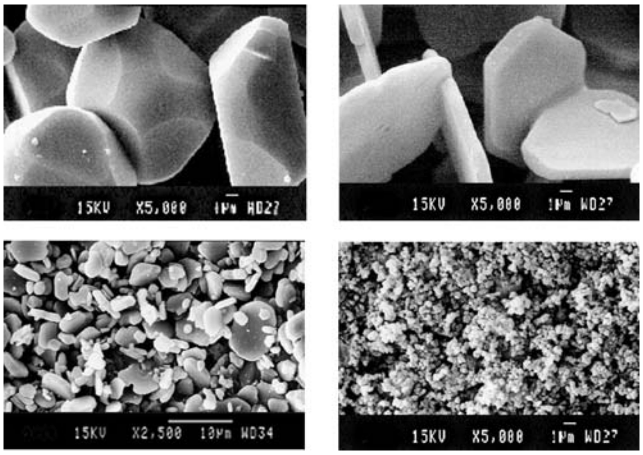

Figure 7.6.15
Examples of morphological forms of ceramic alumina.

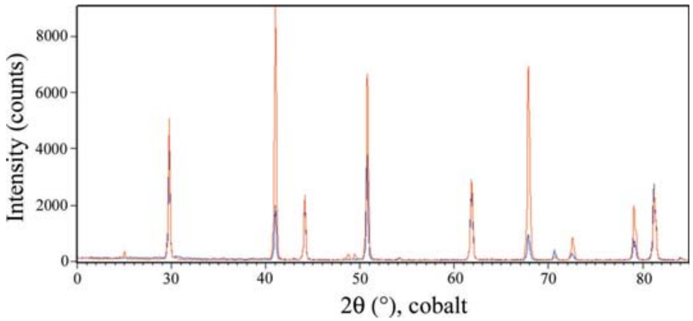

Figure 7.6.16
The superposition of the diffractograms from two ceramic aluminas of different morphology.

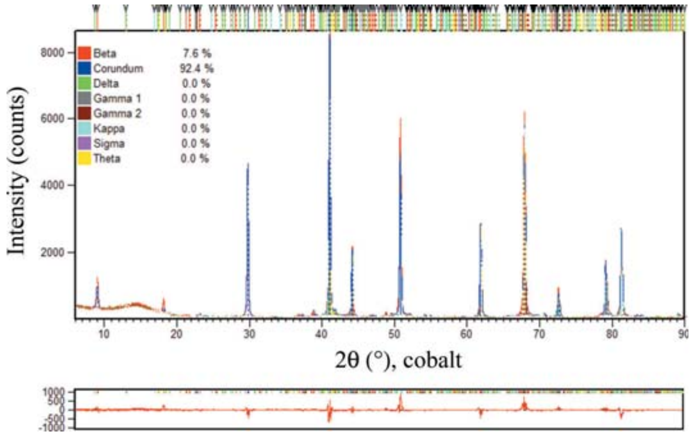

Figure 7.6.17
Example of Rietveld refinement for ceramic alumina.

The estimation of the content of so-called sub-alphas (sub-alphas are phases other than alpha, commonly called transition aluminas) is only possible using the Rietveld method. For the quantification of metallurgical and special aluminas, a dedicated

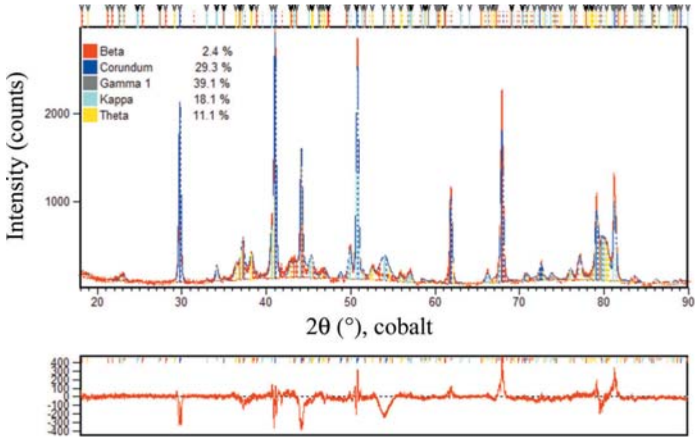

Figure 7.6.18

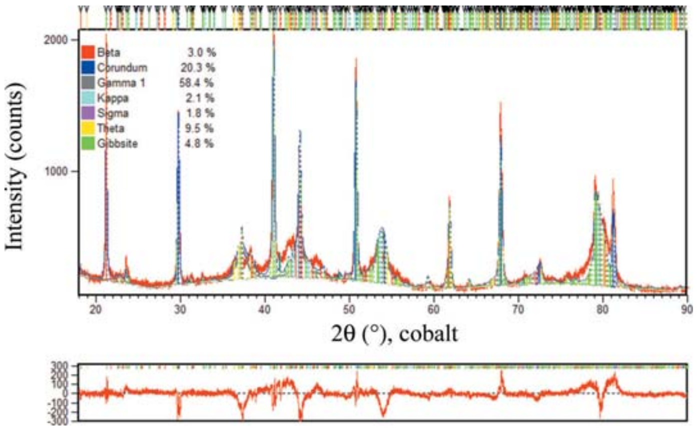

Figure 7.6.19
Example 2 of Rietveld refinement for a sub-alpha specimen.

Rietveld analytical program was written with structure data for eight alumina mineralogical phases: alpha, beta (β-Al_2O_3 = $Na_2O{\cdot}11Al_2O_3$), delta, gamma (two sets), kappa, sigma and theta, and also gibbsite. Figs. 7.6.17–7.6.19 show unique examples of the phase quantification in aluminas of various origin and phase composition using the Rietveld method.

7.6.7. Scrubber alumina

The alumina produced by the Bayer process is used as the feedstock in the Hall–Héroult process for producing metallic aluminium. The alumina is dissolved in molten cryolite, Na_3AlF_6, and electrolysed. AlF_3 and CaF_2 are added to decrease the melting point.

A dry scrubber is the most modern and efficient system generally used to prevent all discharge of pollutants from the aluminium plant. Gases from each pot are exhausted into the dry scrubber in which alumina is used to clean fluorine compounds from the pot gas, and the dust is collected in filter bags. Up to 99.8% of the overall fluorine is removed from the emissions.

Alumina from the dry scrubber, including bound fluorine mixed with dust, is called reacted alumina and is used in the pots as raw material. This recycling of fluorine in the dry scrubber reduces the need to purchase the fluorine materials necessary to operate the pots. Although total F is typically analysed by XRF or by table-top NMR, XRD is called upon periodically to verify an unusual content of reacted alumina or a mixture of alumina and AlF_3. Fig. 7.6.20 gives an example of such analysis. Because most of the sample material is X-ray amorphous, the Rietveld analysis gives an indication of distribution of AlF_3 and crystalline alumina phases.

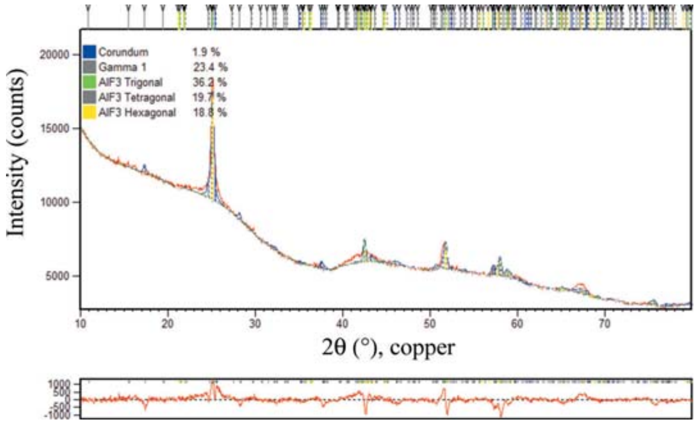

Figure 7.6.20
Rietveld analysis of reacted alumina.

7.6.8. Electrolytic bath

The characterization of the bath electrolyte for process control or for non-routine purposes is generally carried out using only two methods: a combined XRD and XRF method, or by wet chemistry. The wet-chemical methods were historically the first employed in bath-electrolyte characterization. These days, their role has mostly been reduced to certification and quality-control functions. Modern and very efficient industrial characterization of bath electrolyte for potroom process-control purposes involves instrumental XRF–XRD measurement. The instrument (often called potflux analyser or bath analyser) is employed for electrolyte characterization and determination of excess AlF_3 ($ExAlF_3$), bath ratio, Ca and undissolved Al_2O_3 (α-Al_2O_3) in the bath without or with additives. Natural bath standards are required in the instrument calibration.

Significant developments in the quantitative phase analysis of electrolytic bath have taken place in Alcan in recent years (Feret, 2007, 2008). The traditional equation used for controlling bath chemistry,

$$\%ExAlF_3 = 0.2424\%\text{chiolite} + K(\%CaF_2 - \%\text{fluorite}), \tag{7.6.2}$$

was critically examined and was no longer considered valid. Chiolite is $Na_5Al_3F_{14}$. The ($\%CaF_2 - \%$fluorite) term represents the $NaCaAlF_6$ compound, which is not the only Ca-cryolite occurring in bath. It was shown that calcium (in the form of CaF_2) plays a very important role in bath chemistry and is responsible for three major effects: the absorption of diffracted radiation, the formation of $NaCa_{1.5}AlF_7$ (which alters the bath chemistry) and the spectroscopic interference of $NaCa_{1.5}AlF_7$ over chiolite. The occurrence of two diverse Ca-cryolite ($NaCa_{1.5}AlF_7$ and $NaCaAlF_6$) phases in bath-electrolyte samples was identified as the reason for the experimental constant K being different from the theoretical K value of 0.717. Consequently, it was concluded that equation (7.6.2) does not correctly reflect the chemistry of plant samples. Moreover, equation (7.6.2) is sensitive to the crystallinity variation, which is related to the way the bath samples solidify. This situation compromised the control of plant

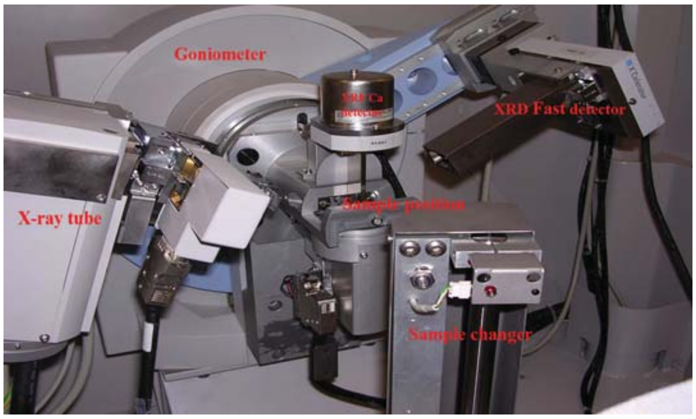

Figure 7.6.21
Hardware configuration of the bath analyser.

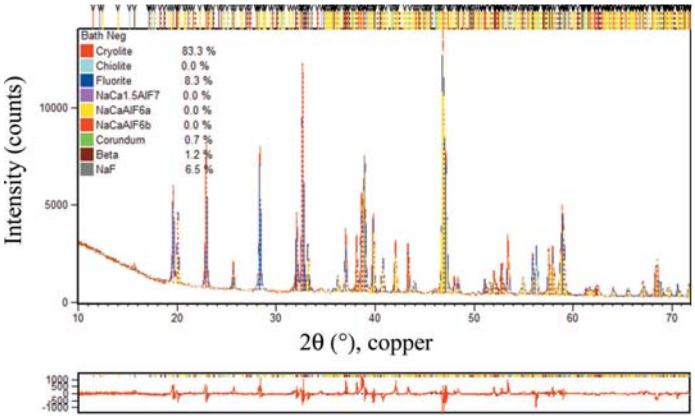

Figure 7.6.22
Rietveld refinement for a bath with negative $ExAlF_3$.

operations and did not allow plant efficiencies to be compared. Therefore, it had to be corrected.

For a successful Rietveld refinement, a good-quality diffractogram is required corresponding to the 10–72° 2θ angular range. Using a conventional diffractometer equipped with a scintillator detector, it takes approximately 1 h to obtain such a diffractogram. Obviously, such a long time would preclude implementation of the Rietveld method in real-time production in the plant laboratory. Therefore, the only possibility for a drastic shortening of the diffractogram acquisition time was introduction of a fast position-sensitive XRD detector (Fig. 7.6.21).

A dedicated control file was created for quantification of phases in bath electrolyte. The file is composed of crystallographic, physical and chemical data corresponding to phases known to occur in bath electrolyte such as cryolite, chiolite, fluorite, $NaCa_{1.5}AlF_7$, $NaCaAlF_6$ (α and β forms), $NaAl_{11}O_{17}$ (β-Al_2O_3), α-Al_2O_3, NaF and $LiNa_2AlF_6$ (Table 7.6.4).

Two other constituents – carbon and metallic aluminium – occasionally occur in bath specimens. Although they do not significantly affect the X-ray procedure, they pose a potential difficulty at the sample-preparation stage. Also γ-Al_2O_3 may occur at low content.

The Rietveld method gives concentrations of individual phase constituents that obviously allow calculation of total $ExAlF_3$. The $ExAlF_3$ is present in chiolite and two Ca-cryolite phases (Feret, 2007, 2008). The $ExAlF_3$ concentrations are calculated as follows:

$$\begin{aligned}\%ExAlF_3 = {} & a(\text{chiolite}) + b(NaCa_{1.5}AlF_7) + c(NaCaAlF_6)\\ & + d(NaF) + e(LiNa_2AlF_6),\end{aligned} \tag{7.6.3}$$

where a, b, c, d and e are stoichiometric constants.

Figs. 7.6.22 and 7.6.23 give examples of Rietveld refinement for bath samples. Fig. 7.6.24 shows the correlation between $ExAlF_3$

concentrations determined by WCh and the Rietveld method. Using Rietveld analysis, the $ExAlF_3$ concentrations determined for Alcan bath-electrolyte standard samples correspond very well with those determined by WCh. The standard deviation of the slope is ±0.34% and the repeatability established from analysis of the same sample is ±0.10%.

Until recently, wet chemistry was the only existing primary methodology used in the determination of $ExAlF_3$. At present, Rietveld can now be considered as another primary method used for this purpose. As Table 7.6.5 demonstrates, the Rietveld method of bath analysis offers many advantages over the conventional XRD method. In addition, using the bath-phase composition from the Rietveld method, one may calculate additional process parameters, for example the liquidus temperature.

7.6.9. Spent potlining (SPL)

Spent potlining (SPL) originates from the internal lining of the aluminium electrolysis cell and is composed of refractory bricks and carbon mixed up with electrolytic bath components (Pawlek, 2012) The SPL must be removed and replaced every few years of cell service. Globally, aluminium smelters produce in excess of 500 000 tonnes of SPL each year. As it is contaminated with fluorides and cyanides, SPL is classified as hazardous waste. In many cases, SPL is disposed of in landfill, but in several countries regulations require its neutralization. New processes that render the hazardous waste harmless have been developed. Whether prior to processing or after, the material composition needs to be known. The elemental composition is usually determined by XRF, but Rietveld analysis remains irreplaceable in phase-composition determination. The typical variation of the major phase constituents is very large and depends on an individual batch of material. Among the major mineralogical components one can name are carbon, graphite, cryolite, chiolite, fluorite, corundum, β-alumina, NaF, TiB_2, nepheline, quartz and albite. Analytical information is needed for the preparation of a balanced mixture of refractory, carbon and bath-input constituents to assure optimum performance of the neutralization process. Also, depending on the process, Rietveld analysis allows confirmation of the process effectiveness in the elimination of harmful F-containing phase constituents. For example, in the Alcan Low-Caustic Leach and Lime Process (LCLL), the finely ground SPL is leached with caustic to remove the fluorine, free and complexed cyanide, alumina and some silica into the leach liquor (Hamel *et al.*, 2009). Among the F-containing phases, only CaF_2 is left, which is neutral. After washing, the carbon-rich residue (Fig. 7.6.25) is a potential fuel or reducing material for metallurgical operations.

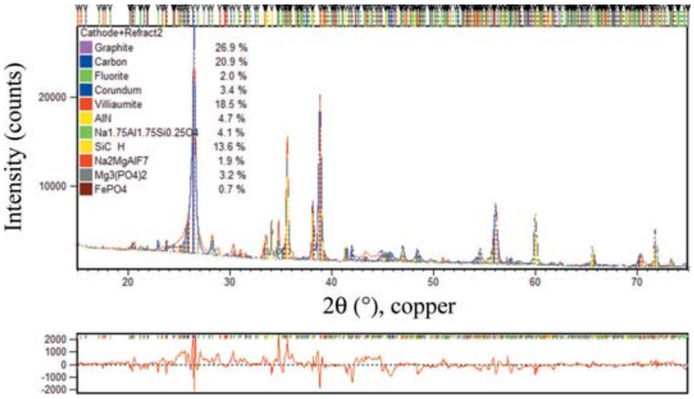

Figure 7.6.25
Rietveld refinement for SPL rich in carbon.

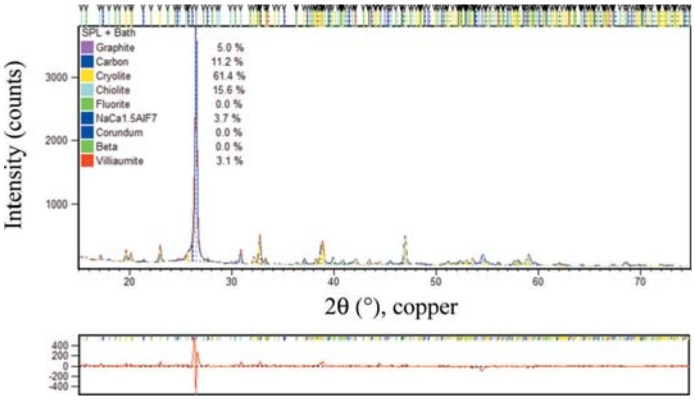

Figure 7.6.26
Rietveld refinement for SPL with bath.

Rietveld analysis not only provides qualitative and quantitative information on the nature of SPL, but also may help to quantify its commercial value before and after the neutralization process. In addition, valuable data such as the product's graphitization rate, estimation of the TiB_2 content (Fig. 7.6.26) and environmental risks are obtained.

7.6.10. Dross

Dross is the residual waste material produced from any process in which aluminium is melted and when the metal comes into contact with air. Dross usually comprises aluminium oxides, aluminium nitride, other metal oxides and minerals originating from scrap or contaminants (as salts) from melting furnaces (chlorides, sulfides, fluorides, phosphides, carbides), as well as metallic aluminium. The worldwide aluminium industry produces nearly five million tonnes of furnace waste each year and around 95% of this material is landfilled, costing the industry an estimated 80 000 000 US dollars. New regulation and spiralling costs are forcing the industry to consider alternatives.

Dross is usually crushed first. Then aluminium is separated from it to obtain aluminium dross residue, which is also known as non-metallic product (NMP). Other methods employed to separate Al metal from dross are known, and each requires information about the material content (Kevorkian *et al.*, 2013). Sodium-removal efficiency for chlorine and salt injection also

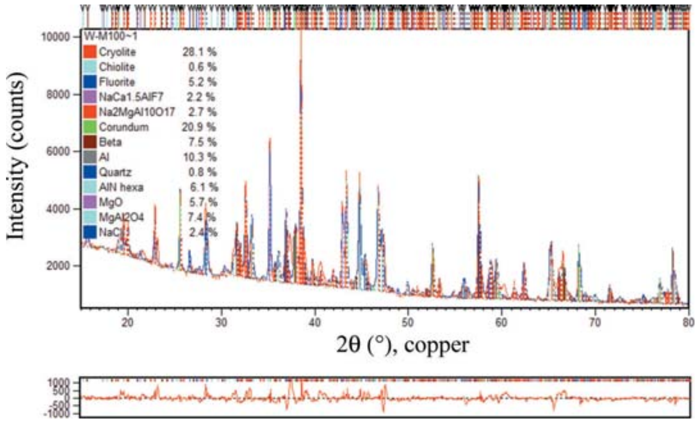

Figure 7.6.27
Example 1 of dross analysis.

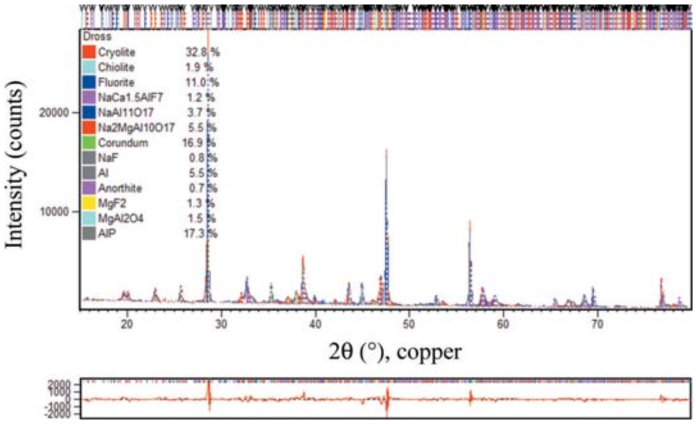

Figure 7.6.28
Example 2 of dross analysis.

requires monitoring. Figs. 7.6.27 and 7.6.28 give examples of dross analysis.

One of the difficulties with Rietveld analysis of dross is the constantly changing composition, as practically every furnace has different work parameters (Gomez *et al.*, 2008).

7.6.11. Discussion

As the aluminium-industry requirements for better process and quality control become more stringent, applications of the Rietveld method have been steadily increasing. From the technological beginning of aluminium manufacture (bauxite) to the final manufacturing processes, there is and will continue to be a place for Rietveld analysis. The choice of a suitable X-ray instrument will always depend on the price and performance ratio and will be dictated by a particular application. The advantage of XRD as an analytical instrument lies in the variety of characteristic parameters it can measure, simplicity of sample preparation and the ability to run the analysis of a series of samples in an automatic mode. Hence, XRD is capable of responding to today's laboratory demand for even greater flexibility and task multiplicity. Given the fact that future applications of the Rietveld method will be extended to materials such as new ceramics, environmental samples and composites, it is obvious that XRD will remain a universal and a very appealing analytical tool for the aluminium industry.

In addition to those materials that are mentioned in Table 7.6.1, there are others which are analysed more infrequently by the Rietveld method. Among them one can name fluorspar (CaF_2), AlF_3 and, recently, grey mud. The latter is predominantly composed of extremely oriented corundum crystals that precipitate from the electrolytic bath and cover the bottom of the electrolytic cell.

Accurate determination of Al_2O_3 distributed among various minerals is critically important for the industry, as it affects the material's commercial value and its process performance. It is ambitious to require Rietveld analysis using an X-ray tube diffractogram to become an accurate tool in the phase quantification of the majority of bauxites. Standard Rietveld software cannot consistently provide reliable concentrations of gibbsite, boehmite, Al-goethite or kaolinite (which are considered strategic) for most bauxite cases studied over the years. The major obstacle in the quantification process is the bauxite amorphous content, which originates not from one source, but from several sources simultaneously. There are numerous examples of bauxite diffractograms with missing representation of boehmite, kaolinite or Al-goethite, yet occurrence of these phases is confirmed by other methods. The total amorphous content of the bauxite matrix can obviously be quantified using the internal-standard method, but assigning its parts to individual mineralogical constituents is difficult or impossible employing XRD alone (see Madsen & Scarlett, 2008).

The use of synchrotron radiation is a powerful alternative to using radiation from an X-ray tube, but it is not a panacea. It facilitates the detection of amorphous material, but the glass capillary usually used to contain the specimen is itself amorphous. Nevertheless, synchrotron-radiation diffractograms offer substantial advantages over diffractograms from an X-ray tube – including higher count rates and improved signal-to-noise and peak-to-background ratios, and resolution. Whether using synchrotron radiation or an X-ray tube, a diffractogram is seldom a sufficiently complete representation of the mineralogical content of a bauxite sample. Gibbsite, being the most abundant phase and occurring with amorphous aluminium hydroxides, is the major victim of the Rietveld analysis of bauxite. Only very well crystallized bauxite from selected deposits can be successfully analysed, at least for certain mineralogical constituents. Diasporic bauxite shows a better chance for successful phase quantification (Nong *et al.*, 2007). New non-PXRD methods are emerging (*e.g.* mathematical modelling) (Kimmerle *et al.*, 1997), which erode some traditional applications of WCh and the Rietveld method.

Routine analysis of the phase composition of electrolytic bath for cell process control by the STARprobe method has recently been proposed (Wang *et al.*, 2011). The STARprobe does not require a laboratory and accelerates analysis. However, the STARprobe requires 4–5 min operator contact time per sample, does not apply to baths with negative $ExAlF_3$, or to baths with Li or Mg additives, is costly to use and provides results that are inferior in quality to the Rietveld method. The average XRD instrument lifespan in industry is 12–15 years, and that of the automatic sample-preparation equipment is much longer. The estimated cost per sample is therefore the lowest possible, despite high initial investment. Consequently, the STARprobe may remain a convenient, but more expensive, alternative to Rietveld in bath analysis.

This chapter contains material previously published in Feret (2013), which is reproduced with permission from JCPDS-International Centre for Diffraction Data. The author would like to express his gratitude to the management of the Arvida Research and Development Centre of Rio Tinto Alcan in

Jonquiere for permission to publish different parts of this material at various times. The editors of the volume are sincerely thanked for their suggestions for modifications to this chapter, and Ryan Provost is also thanked for providing diffractograms of dross and potlining for this review.

7.7. Mining and mineral processing

N. V. Y. Scarlett and D. L. Bish

7.7.1. Introduction

The history of mining and mineral processing effectively mirrors the history of civilization, and stone and metal have been mined since prehistoric times. Early mining involved the acquisition of native materials from close to the Earth's surface, whereas more complex excavation and subsequent metallurgical developments lent their names to the 'Three-Age System' of archaeological chronology (Heizer, 1962) developed by Christian Jürgensen Thomsen (1788–1865), which is still in common usage. The three ages are (i) the Stone Age, which lasted for approximately 3.4 million years, ending sometime between 4500 and 2000 BCE, (ii) the Bronze Age, which takes its name from the smelting of copper and tin together and occurred at various times in different parts of the world over a period from about 3600 to 300 BCE, and (iii) the Iron Age, the occurrence of which was similarly variable but extended from about 1300 BCE to 500 AD. The so-called 'Father of Metallurgy', Georg Agricola, published the volume *De re Metallica* (Agricola, 1912) in the 16th century, which detailed the technology of mining and metallurgical processing as it was understood at the time.

The modern 'resource sector' deals with the mining and processing of a range of nonrenewable resources in the mineral and energy streams. Many industries are connected with and dependent upon this sector, and much of society is subsequently reliant on the resulting products. Examples of some of these are given below.

(i) Building materials such as rocks (direct) and cement/bricks *etc.* (indirect; see Chapter 7.12 for more information on cement).

(ii) Steelmaking for use in civil engineering, transport, appliances, tools *etc.*

(iii) Ceramics, which are generally categorized as structural (*e.g.* bricks, tiles, pipes), refractories (*e.g.* furnace linings, crucibles), whiteware (domestic uses) and technical (*e.g.* biomedical implants, composite materials for aerospace applications). (See Chapters 7.8 and 7.9.)

(iv) Energy such as oil and natural gas, steaming and coking coal, coal seam methane gas and uranium (see Chapter 7.11).

(v) Agricultural applications such as the use of limestone to increase calcium content, to correct soil acidity and to provide calcium to animal and poultry feeds.

(vi) Glasses such as soda-lime glass (windows, drinking vessels), network glasses (fibre optics, solid-state storage media) and amorphous metals (achieved by rapid cooling from melt).

(vii) Precious metals and stones used for jewellery and other ornamentation.

(viii) Rare-earth elements used for electronics, batteries, magnets, lasers, alloys and catalysts.

The removal of nonrenewable resources from the Earth has potentially negative impacts on the environment that have resulted in the introduction of legislation across much of the world to mediate these effects. This has led to increased research in such areas as environmental management, site remediation and CO_2 sequestration.

Mining and mineral processing are concerned with the extraction of valuable metals and minerals from the earth and the separation of these minerals from the perceived wastes associated with them. There are several stages within these processes, and although details are generally specific to a particular ore body, there are several commonalities. Firstly, the ore body must be discovered. This is typically achieved by a process of exploration or prospecting. The ore body must then be assessed for quality and extent to determine the feasibility (physical and economic) of its recovery. If deemed to be feasible, the ore must then be physically extracted from the earth and treated in such a way as to make the valuable minerals accessible. At the conclusion of the life of a mining operation, the land must be regenerated or reclaimed for future use.

7.7.2. Use of powder diffraction in mining and mineral processing

By definition, mining and mineral processing rely upon mineral assemblages. Identifying, understanding and assessing these assemblages are vital to the successful extraction of the valuable resources. In this context, powder diffraction is particularly useful, as it allows a direct measurement of mineralogy rather than either inferring it from measured chemistry, spectroscopy or assessment *via* optical microscopy. Diffraction methods probe the crystal structural nature of solids, which is essentially the basis of the definition of minerals and other crystalline solids. Although spectroscopic methods, such as infrared or Raman, can be deployed remotely, they are derivative and are not directly related to crystal structure. Optical microscopy is labour-intensive, operator-dependent and severely impacted by sampling errors. This is particularly evident on the scale on which mining operations are conducted. Much of industry relies upon the measurement of bulk chemistry as a routine part of its operation and control. The measurement of bulk chemistry is relatively fast and convenient in an industrial environment. It can also be very accurate and precise. It can, however, only be partitioned into mineral phases based upon prescribed equations that cannot deal with the complex compositional variability that is inherent in many mineral suites. In addition, this approach does not have the ability to discriminate between polymorphs, *i.e.* materials with the same chemical composition but different crystal structures (and thus different physical properties). This approach is also highly dependent on representative sampling. An example of this type of calculation is the Bogue method (Bogue, 1929), which has long been an industry standard for the production of Portland cement (see Chapter 7.12). This method partitions the chemical analyses into individual phases (minerals) in a predetermined sequence based upon preset phase compositions. The greatest source of error in this method is the variability in the individual phase compositions, which has been confirmed by previous electron-probe microanalysis (Madsen & Scarlett, 1999), along with the exclusion of minor phases from the

Copyright © 2019 International Union of Crystallography

method (Taylor, 1989). Further discussion of the errors in these methods can be found in Madsen & Scarlett (1999) and references therein.

Electron-microscopy (EM) methods such as mineral liberation analysis (MLA; Gu, 2003) and QEMSCAN (Gottlieb *et al.*, 2000) have also been employed to determine mineralogy, but are still based upon phase calculations from microchemistry. EM methods can be accurate and precise, but involve labour-intensive sample preparation and relatively slow acquisition times. Even more so than with bulk chemical methods, sampling with EM methods is a significant issue, and it is often difficult to obtain an accurate representation of the true bulk chemistry. EM methods for the determination of mineralogy are also based on prior knowledge of phase chemistries, but can cope better with compositional variability. A significant advantage of EM methods is the parallel acquisition of spatial information, which can provide an indication of the mineral associations and degree of 'liberation', both of which can have a bearing on the separation techniques required for particularly valuable minerals.

Infrared (IR) and Raman spectroscopic techniques are becoming more common in the determination of mineralogy for mineral exploration. These techniques are appealing in that minimal sample preparation is required, data acquisition is rapid and the equipment can be portable. With appropriate equipment and a digital spectral database, this technique may be used in the laboratory, in the field (or with drill cores) or on a large scale during the acquisition of data for mineralogical maps. However, the low penetrating power of the IR beam makes it a surface-specific technique and it is therefore in essence semiquantitative (Madsen *et al.*, 2013). Raman spectroscopy is particularly susceptible to fluorescence effects, detracting from the general applicability of the method in the field. Although the signals in IR and Raman spectra are obtained directly, they must be calibrated against known library standards or independent data such as quantification *via* powder X-ray diffraction.

As emphasized above, powder diffraction has the potential to provide a direct measurement of the mineralogy of a sample. Such an analysis may take the form of a qualitative assessment where the component phases of a mixture are identified, it may be semi-quantitative based upon the relative peak heights (or integrated areas) of each of the phases giving a 'major, minor, trace'-style analysis, or it may be fully quantitative. Quantitative phase analysis (QPA) in this environment may be assessed with a high degree of precision, but there are many factors that determine the absolute accuracy of such measurements. These are discussed along with detailed methodologies in Chapter 3.9 of this volume. As with the other methods discussed above, powder-diffraction analysis may also be subject to sampling errors. However, modern inline, online and robotic systems have the potential to minimize these.

7.7.2.1. *Areas of applicability*

There are a number of operations in the mining and mineral processing industries where the application of powder diffraction can be beneficial. Traditionally, identification of the minerals present and estimation (or quantification) of phase abundances are the primary goals of X-ray powder diffraction. However, with the increased requirements to exploit ores that would not previously have been considered economical, detailed knowledge of crystal chemistry, crystallite size and amorphous content have become more important.

During the exploration stage, phase identification in drill cores is critical as an aid to the location of valuable ore bodies. An estimate of relative phase abundances is necessary to provide an assessment of ore grade and to determine the ease or otherwise of processing in order to make decisions regarding the economic feasibility of extracting the valuable minerals from an ore body. More detailed geometallurgical knowledge of the ore will determine the subsequent processing steps and will allow the most efficient choice of grinding regimes, reagents, waste separation and handling procedures, *etc.*

Knowledge of the mineralogy and chemistry of a system is vital at all processing points from the mine to the final product. Powder diffraction can serve as a valuable tool for determining the degree of concentration or separation during mineral dressing, the purity and form of mineral products during the extractive metallurgy phase, the quality of waste products that may be required for compliance with environmental legislation, and the quality control of the final product (for example iron-ore sinter, Portland cement, metal sheet *etc.*). Powder diffraction can also play an important role in the development of new processes and in the troubleshooting or optimization of existing processes.

7.7.3. Powder-diffraction methodology

7.7.3.1. *Equipment and data collection*

The data-collection strategies employed and the experimental setup used for diffraction measurements will depend wholly on the situation and the information required from the analysis. For example, equipment used in the field or plant will generally differ greatly from that used in the research laboratory. When choosing equipment and a data-collection strategy, consideration must be given to time-frame requirements, whether qualitative or quantitative analysis is required, the lower limits of detection required, whether or not detailed structural information is necessary, and whether the data collection must be static or dynamic. Detailed discussion of the types of instrumentation available and the options for data processing and analysis are given in Parts 2 and 3 of this volume and in other texts on the subject of diffraction in general (Chung & Smith, 1999; Cockcroft & Fitch, 2008; Klug & Alexander, 1974).

By far the most commonly used diffraction equipment in the mining and mineral processing context is the laboratory diffractometer employing an X-ray tube with a particular anode as the source. This instrument may be deployed in a variety of configurations for a range of situations, including process and quality control (on location in plants and at mine sites) and process development and optimization (within research facilities). Equipment specific to data collection in field environments will be discussed in Section 7.7.3.1.1 below. The data-collection parameters for each situation will very often be determined by the desired outcomes from the data obtained and established *via* prior research into the system under investigation. For example, routine 'scan and identify' data may generally be collected much more rapidly and at lower resolution than data required for quantitative phase analysis. However, prior research may be able to optimize the methodology so that more rapidly acquired, poorer quality data may be used for quantitative phase analysis within a restricted parameter set. Advanced radiation sources such as neutron and synchrotron facilities are generally the province of research applications. Thus, in the context of the subject of this chapter, they are usually restricted to the development phases of mineral process design and to fundamental

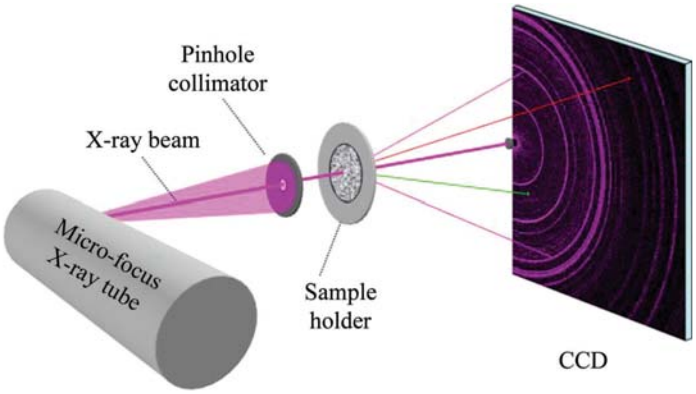

Figure 7.7.1
Overall geometry of CheMin (reproduced from Sarrazin, Blake *et al.*, 2005).

studies related to geological processes that may be of subsequent use in exploration operations.

7.7.3.1.1. *In-field diffraction*

Planetary exploration has been a driving force behind the development of truly portable, automated *in situ* powder X-ray diffraction (PXRD) instrumentation (Blake *et al.*, 1994; Vaniman *et al.*, 1991). Vaniman and co-workers described the potential for combined PXRD and X-ray fluorescence (XRF) for planetary surface analyses, with emphasis on the ability of PXRD to provide definitive mineral identification based upon crystal structure (*i.e. via* diffraction). They cited Mars as a 'good example of a planet where the capabilities of PXRD will be critical for adequate *in situ* surface exploration'. The goals of planetary exploration and exploration in the mining context are not dissimilar. The mineralogical analyses that help to locate and describe an ore body also provide information regarding the pressure and temperature conditions of formation necessary to establish the origin and provenance of a sample and the environmental history of a planet.

The CheMin instrument was developed as part of the NASA planetary exploration efforts and is an integral part of the scientific payload on the Mars Science Laboratory (Blake *et al.*, 2012; Sarrazin, Blake *et al.*, 2005). CheMin is a miniaturized PXRD/XRF instrument (Fig. 7.7.1) that uses transmission geometry and a low-power Co X-ray source to provide both XRF and PXRD data from a small vibrated powder sample. Energy-dispersive X-ray fluorescence spectra are collected by a two-dimensional charge-coupled device (CCD) detector that provides both spatial and energy resolution. Analysis of the two-dimensional distribution of CCD pixels impacted by characteristic X-ray photons (Co $K\alpha$ in this case) provides a two-dimensional diffraction pattern of the sample. These two-dimensional diffraction data can be integrated circumferentially to create a one-dimensional diffraction pattern that can be analysed by conventional methods, including Rietveld methods or other full-pattern methods such as *FULLPAT* (Chipera & Bish, 2002). The latter allows the analysis of both crystalline and amorphous materials.

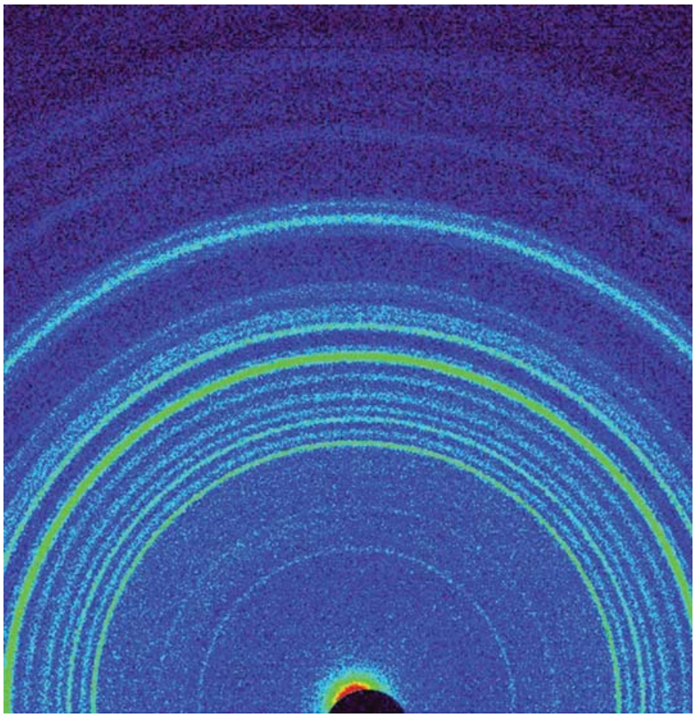

Figure 7.7.2
Two-dimensional X-ray diffraction pattern (Co $K\alpha$) of soil from the Rocknest aeolian bedform. This pattern is of scoop 5 and represents the sum of 63 half-hour frames. The black circle at the bottom of the image is the shadow of the beam stop.

The CheMin instrument is on board the Curiosity rover on the Mars Science Laboratory, which landed in Gale Crater on Mars on 5 August 2012. To date, the instrument has analysed 14 drilled samples and two scoop samples, along with several onboard standards. CheMin first analysed the <150 µm fraction of an aeolian bedform (*i.e.* a dune), which provided the first X-ray diffraction pattern obtained on another planet (Bish *et al.*, 2013, 2014). Fig. 7.7.2 shows the two-dimensional diffraction pattern for this material. Fig. 7.7.3 illustrates the results of Rietveld refinement using the one-dimensional data. The dune material, which consists of both fine-grained material of a global nature and more locally sourced coarser material, contained the typical basaltic minerals plagioclase, Fe-forsterite and two pyroxenes, with minor amounts of other silicate, oxide and sulfate minerals, most of which are

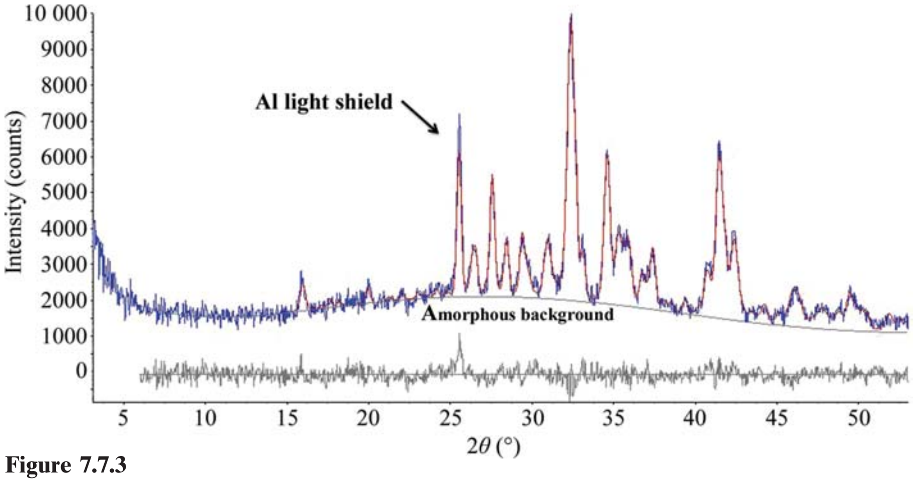

Figure 7.7.3
Conventional one-dimensional X-ray diffraction pattern derived from the data in Fig. 7.7.2. Observed data are in blue and the red plot represents the results of Rietveld refinement. The grey plot near the bottom represents the difference between observed and calculated patterns. Significant scattering contribution from amorphous components is visible in the 20–45° 2θ range. The unfitted intensity just above 25° 2θ is due to the aluminium light shield.

present near detection limits (Table 1 in Bish *et al.*, 2013). The dune material also contains considerable amorphous material (∼27%), and it is noteworthy that no hydrous crystalline components were identified. Independent evolved-gas analyses by the Sample Analysis on Mars (SAM) instrument on the Curiosity rover revealed several wt% H_2O in this sample, demonstrating that the amorphous component is hydrous. Subsequent PXRD analyses of two drill-hole samples of a mudstone revealed similar mineralogy, with the addition of a trioctahedral smectite, bassanite ($CaSO_4{\cdot}0.5H_2O$), considerable magnetite and little Fe-forsterite. The differences in mineralogy can be explained by the alteration of an Fe-forsterite-rich precursor to a mudstone containing magnetite and Fe-saponite. The successful demonstration of remote PXRD on another planet demonstrates the feasibility of performing PXRD in virtually any environment, with or without human intervention. In this case, the sky is no longer the limit.

One of the major difficulties in employing an *in situ* powder-diffraction instrument is that of sample preparation. An ideal powder-diffraction sample requires that effectively an infinite number of crystallites in all possible orientations be presented to the X-ray beam. This is not achieved in practice, but may be approximated by finely grinding and homogenizing the sample prior to data collection. *In situ* samples are likely to be coarse-grained and inhomogeneous. In order to overcome this requirement, the CheMin instrument uses a sonic vibrating sample holder that effectively increases the number of crystallites in the X-ray beam, thereby allowing the characterization of poorly prepared or oriented samples (Sarrazin, Chipera *et al.*, 2005). This development is of vital importance for an instrument designed to operate completely independently in a remote location (such as Mars).

The stimulus of space exploration often provides technology that ultimately yields benefits for terrestrial applications. Technologies developed for the CheMin instrument have been used in inXitu's (inXitu Inc., California; now owned and marketed by Olympus) portable transmission PXRD/XRF instrument (Terra), which is designed specifically for rock and mineral analysis in the field. It is self-contained with on-board software for producing conventional one-dimensional PXRD patterns and XRF spectra within minutes. The instrument is contained in a large suitcase and will operate for ∼4 h on a single charge. The transmission geometry of the instrument has been optimized using ray-tracing simulations to improve both resolution and intensity, and useful diffraction data can often be obtained in less than 5 min, making it a potentially powerful field exploration tool. The Terra instrument also uses the sonic vibration sample holder developed for CheMin, which allows the user to analyse poorly ground materials with ease. The Terra instrument can communicate wirelessly with an external computer, and data may thus be analysed in the field.

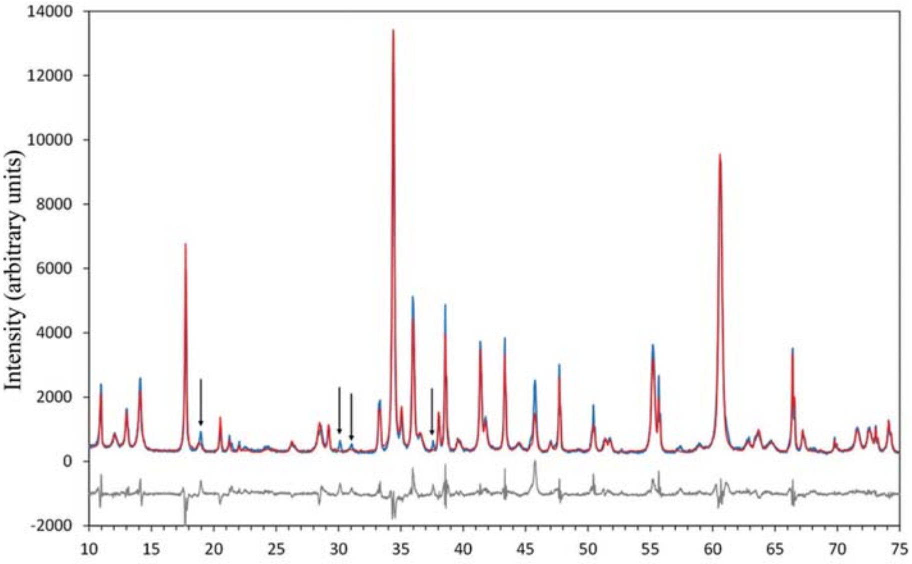

Figure 7.7.4
Diffraction pattern (Co *Kα* radiation) of nickel concentrate (blue) with calculated profile from a Rietveld refinement model (red) incorporating the following phases: pyrite, 17%; pentlandite, 51%; magnetite, 12%; magnesite, 5%; violarite, 3%; pyrrhotite, 3%; talc, 4%; hydrotalcite, 0.4%; lizardite, 4%; honessite, 1%. There are also several unmatched peaks indicating unidentified material in the sample (indicated by vertical arrows).

The CheMin instrument also spawned another PXRD/XRF instrument that is useful for *in situ* application. The Duetto instrument, also from inXitu (Chiari, 2008; Sarrazin *et al.*, 2008), was developed jointly with the Getty Conservation Institute specifically for non-invasive examinations of works of art. The Duetto instrument differs from CheMin and Terra primarily in the mode of sample presentation. Duetto operates in reflection rather than transmission mode to allow the examination of large objects *in situ*. The source and detector are as described previously for CheMin, but Duetto also includes an imaging camera for precise location of the area to be sampled. The Duetto instrument can potentially be used wherever sample preparation is not possible or desired, for example for the examination of rock faces or objects of art *in situ*.

Recently Hansford (2016) has proposed methodology suited to a simple, portable instrument of fixed geometry which exploits a method of selectively targeting a phase of interest within a sample. It is an energy-dispersive X-ray diffraction method based around the exploitation of coincidences of diffraction peaks and the ratios of different characteristic X-ray energies. It has potential for *in situ* or in-line use in situations where a particular phase is key to the application under investigation.

7.7.3.2. *Qualitative analysis*

Qualitative analysis in the context of powder diffraction primarily involves the identification of crystalline phases, such as minerals, in a multiphase sample, often referred to as the 'search–match' process. This is described in greater detail elsewhere in this volume (see Chapter 3.9), but usually involves the comparison of observed diffraction patterns with databases of known phases. Identification of the phases present is based on peak positions either alone or in combination with their relative intensities. The manufacturers of diffraction equipment often have proprietary software for this 'search–match' process (for example *PANalytical X'Pert Highscore* (PANalytical BV) and *EVA* (Bruker AXS)], as do the producers of licensed databases such as the ICDD PDF (Powder Diffraction File) products (Fawcett *et al.*, 2017) and the academic projects COD (Crystallographic Open Database; Downs & Hall-Wallace, 2003; Gražulis *et al.*, 2009, 2012, 2015; Merkys *et al.*, 2016) and PCOD (Predicted Crystallographic Open Database; Le Bail, 2005). Non-commercial software is also available (for example *LOGIC* and

CMPR from NIST and *MATCH*) but relies on access to an appropriate database. A Search–Match Round Robin (SMRR) was conducted in 2002 (Le Meins *et al.*, 2002) with the general finding that the expertise of the operator was one of the most important aspects of successful search–match, even when the elemental composition of the sample was known. However, knowledge of the origin of a sample, which allowed the selection of an appropriate PDF subset (organic, mineral, organometallic *etc.*), improved the success rate. The SMRR evaluated four different samples (geological, synthetic chemical, pharmaceutical and industrial processing plant), none of which contained more than four phases. Real geological samples, such as rocks, ores or concentrates, may be very complex and often contain considerably more than four phases, and in general it is recommended that as much information as possible (bulk and/or micro chemistry, origin *etc.*) be gathered about the sample to assist with phase identification. An illustration of this complexity is given in Fig. 7.7.4, which shows the diffraction pattern of a nickel concentrate with the calculated pattern from Rietveld refinement of a model containing ten minerals. Note that not all of the observed peaks are simulated by the model, indicating the presence of one or more unidentified materials.

7.7.3.3. *Quantitative analysis*

Quantitative phase analysis (QPA) often follows the identification process in diffraction analysis. Methods for performing QPA are described in detail in Chapter 3.9. As stated earlier, knowledge of phase abundance in geological samples is useful as part of the exploration process, in the assessment of ore grade and in determining the extent of separation processes in mineral dressing activities. Detailed QPA may also be of benefit during the research phases in order to understand the genesis, alteration, distribution and stability of minerals *etc.*, which may lead to improved processing options.

7.7.3.4. *Crystal structural analysis*

Mining productivity may be affected by the crystal structural features of individual minerals, such as substitutional solid solutions and strain. These may be assessed during the QPA stage of diffraction analysis, particularly if this is performed *via* the Rietveld method (Rietveld, 1969). Examples of such substitutions include Al-for-Fe substitutions in goethite (Fazey *et al.*, 1991), which limit the recovery of Al *via* the Bayer process, and the loss of silver by incorporation into jarosite (Dutrizac & Jambor, 2000), either *via* co-precipitation from hydrometallurgical solutions or by formation during the bioleaching of copper ores. Substitution and subsequent release of heavy metals from mine-waste dumps is also an important environmental issue (Benvenuti *et al.*, 1997). However, although QPA *via* the Rietveld method is a sensitive method for detecting minor changes in unit-cell parameters that result from chemical substitutions, those substitutions that involve trace elements will not generally be detected by diffraction methods.

7.7.3.5. *High-throughput and batch processing*

The ability to accumulate data rapidly in the field, in the plant or during time-resolved experimentation can result in extremely large data suites that may create data-processing and analysis challenges. To solve these challenges, batch-processing and cluster-analysis methods have been developed and applied in order to minimize analyses or to perform them in a semi-automated fashion.

7.7.3.5.1. *Cluster analysis*

Cluster analysis is an approach that facilitates the partitioning of large data sets into smaller subsets based on certain similarities between the component members. In the case of diffraction patterns, the partitioning may be carried out on the basis of the patterns alone or in combination with another property of the

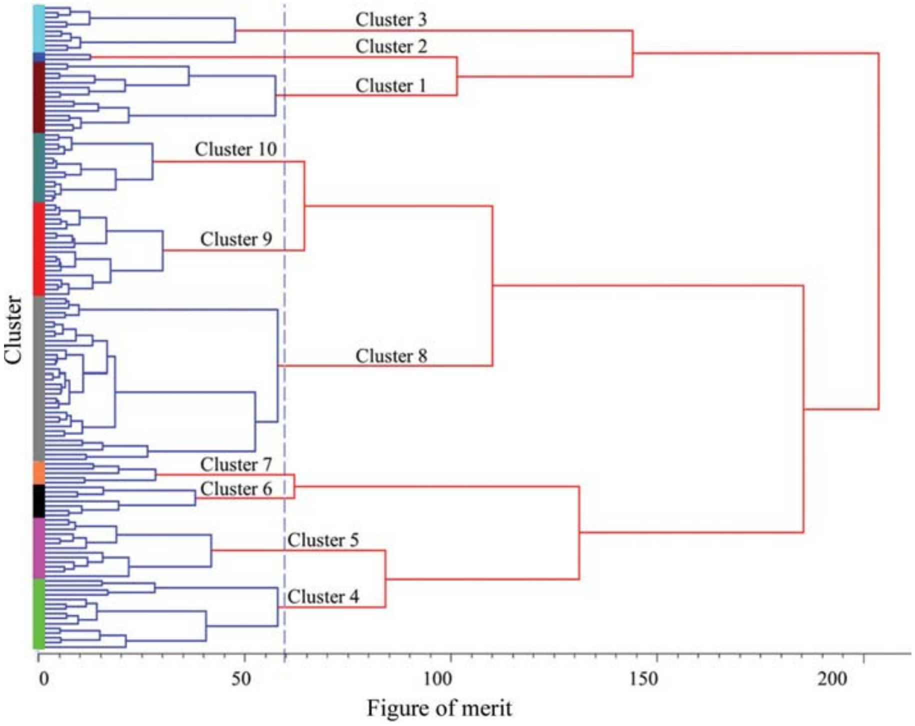

Figure 7.7.5
Dendrogram output from cluster analysis of the data suite collected during the decomposition of plumbojarosite. The vertical dotted line indicates the manually chosen cutoff point which determines the number of clusters into which the data are partitioned. The individual clusters are labelled and coloured using the same scheme as in Fig. 7.7.6.

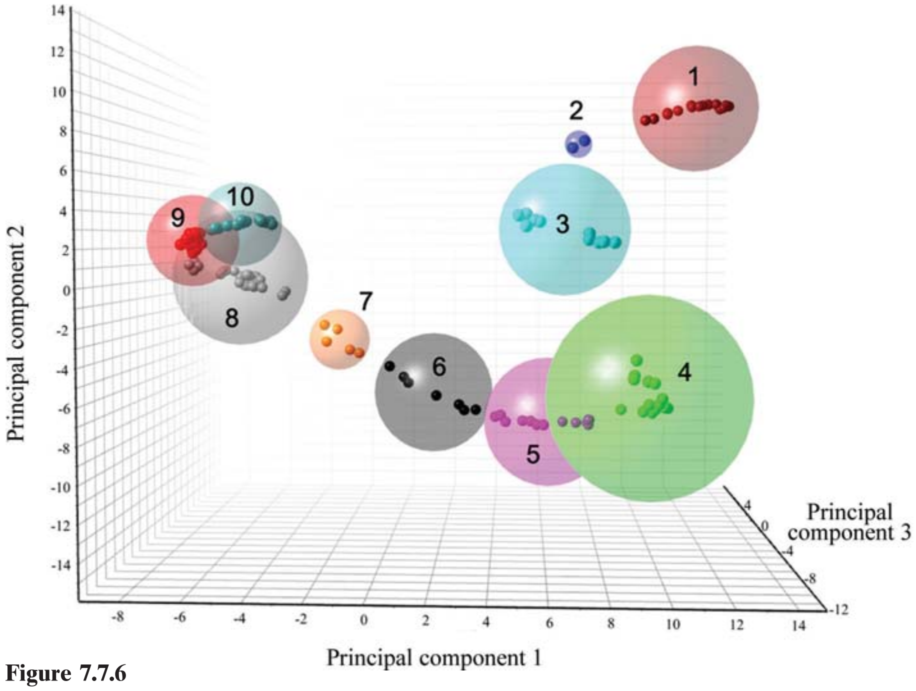

Figure 7.7.6
PCA output from cluster analysis of the data suite collected during the decomposition of plumbojarosite. The clusters are labelled and coloured in accordance with the dendrogram in Fig. 7.7.5.

samples (for example, chemical composition, processing conditions *etc.*). Agglomerative hierarchical cluster analysis begins by considering each member of a data set to be an independent cluster and then progressively merging them on the basis of their similarity. The output can be displayed as a dendrogram which shows the grouping of scans from a low (all scans independent) to a high (all scans contained in a single cluster) figure of merit (Fig. 7.7.5; see Chapter 3.8). Principal component analysis (PCA) may also be conducted as an independent method to assist with visualization and assessment of the quality of the clustering. The principal components of a data set are the directions within it where the variance is greatest. By re-framing the data to these principal components the dimensionality of the data set may be reduced. The position of each member of the data set may then be plotted within this framework as shown in Fig. 7.7.6. Further validation of the clustering may be achieved using techniques such as 'silhouettes' or 'fuzzy clustering' (Barr *et al.*, 2004*b*).

Cluster analysis has clear application in the areas of ore sorting and process control, where large numbers of samples may be assessed and grouped with respect to the desired parameters (for example, geological location, processing time/temperature, ratio of particular phases such as haematite/magnetite *etc.*). This methodology is also useful for partitioning the large data suites resulting from time-resolved experimentation. Fig. 7.7.7 shows an example of such clustering using a data set collected during the thermal decomposition of plumbojarosite (Madsen *et al.*, 2010). The accumulated diffraction patterns are viewed down the *z* axis and the plot has been partitioned according to the clustering shown in Figs. 7.7.5 and 7.7.6.

The most representative pattern from each cluster is reported with the results and may be analysed in detail according to the information required from the analysis (search–match, QPA, crystal structure analysis). An analytical method can then be developed that may be applied to other members of the cluster in a more automated fashion. Some available software packages will also denote the two most extreme patterns in each cluster and identify any outliers that do not fit within any subset of the data suite (König *et al.*, 2010). Software packages such as *Poly-SNAP* (Barr *et al.*, 2003, 2004*a*, 2009; Barr, Dong, Gilmore & Faber, 2004; Gilmore *et al.*, 2004) employ a similar range of clustering tools and can also perform automated, non-Rietveld QPA given an appropriate database of pure phases.

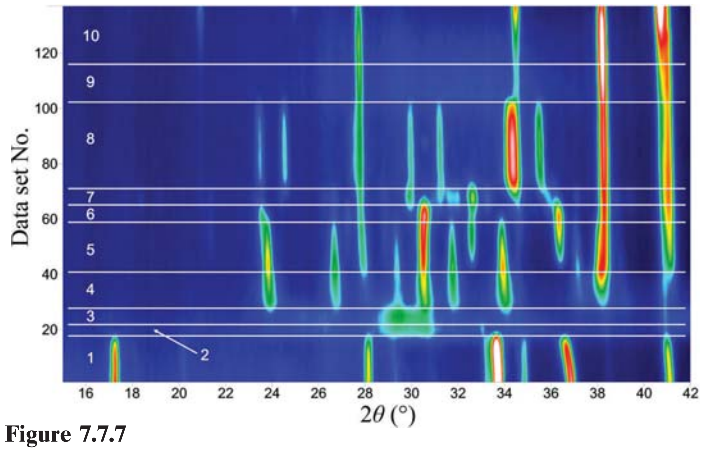

Figure 7.7.7
Accumulated laboratory PXRD patterns from the thermal decomposition of plumbojarosite. The data are represented as a three-dimensional plot with diffraction angle ($2\theta°$) along the *x* axis, data-set number along the *y* axis and intensity along the *z* axis. The white lines approximately delineate the identified clusters within the data suite and the numbers correspond to those in Fig. 7.7.6.

7.7.3.5.2. *Batch processing*

Batch processing is a method for automatically analysing multiple data sets, either sequentially or in parallel. In some instances a group of diffraction patterns must be analysed using identical starting parameters for either search–match or Rietveld analysis. In other cases, an evolving method must be employed to provide appropriate starting parameters for a continuous sequence of data with, for example, time, temperature or geographical distance as a variable. In the latter case, it may be useful to partition the entire data suite at the outset of the analysis in order to determine appropriate starting parameters based upon the most representative patterns from each group as determined by the clustering process (Section 7.7.3.5.1). Stinton & Evans (2007) devised a method of parametric Rietveld refinement that is a form of batch processing in which an entire suite of data is used simultaneously to refine a single evolving model. This allows the refinement of fewer independent variables and a reduction in the degree of uncertainty in parameters that remain constant for the entire suite. It is also possible *via* this technique to refine noncrystallographic parameters such as temperature and kinetic rate constants directly from the diffraction data. Such methodology requires the use of a Rietveld package such as *TOPAS* (Bruker AXS, 2009) that allows the inclusion of user-defined equations into its models without access to the source code.

7.7.4. Examples

7.7.4.1. *Exploration*

The presence of alteration envelopes around hydrothermal ore deposits is often used as a tracer in ore exploration. Traditional methods involve visual and optical microscopic evaluations, but mineralogical logging of drill samples by PXRD can supplement and provide more reliable and consistent analysis than these methods, many of which are operator-dependent (Hausen & Odekirk, 1991). PXRD analyses may be used during the mineral-mapping process to determine the nature and extent of the alteration halo around an ore body, and the *in situ* field-based methods described above have the potential to streamline and speed up such assessments. Hausen & Odekirk (1991) have described in detail the application of such a methodology to drill samples from gold-mining and copper-mining operations. PXRD analyses are also valuable for testing and verifying the results from other mineral-mapping techniques such as the airborne visible/infrared imaging spectrometer (AVIRIS; Rockwell *et al.*, 2006).

7.7.4.2. *Process control*

7.7.4.2.1. *Phosphate mineralogy*

Mintek of South Africa was one of the first organizations to employ real-time on-stream PXRD analysis for use with slurries in the phosphate industry (De Villiers *et al.*, 1983). Online analysis was developed to solve process-control problems that were not satisfied by the existing XRF-based instrumentation. The primary drawback of the XRF approach was an inability to analyse elements lighter than calcium, resulting from the absorption of fluorescent X-rays by the slurry medium (water). To compensate for these drawbacks, Mintek devised a PXRD instrument using Mo $K\alpha$ radiation to detect minerals containing phosphorus, silicon and fluorine in a $\sim$20 wt% solid slurry flowing at 2.5 l min^{-1}. This instrument provided good sampling, and the results were comparable to those provided by wet-chemical methods.

7.7.4.2.2. *Cement*

The US Geological Survey Mineral Commodity Summaries January 2017 lists world cement production for 2016 as $\sim$4.2 million metric tonnes (US Geological Survey, 2017). Cement is a key material for the building and construction industries across the world, and the quality of the final products made from cement is dependent upon the phases present in it and their relative abundances. Phase abundances are traditionally determined during cement production by optical microscopy or normative calculations from chemical analyses (*i.e.* the Bogue method discussed in Section 7.7.2 above).

PXRD is a more direct method of QPA for cement, and much development has been carried out by major diffraction-equipment manufacturers to improve the ease and accuracy of analysis. The approach taken generally incorporates high-throughput instrumentation using automatic sample changers, rapid detectors and automated Rietveld analysis (see, for example, Section 7.7.4.2.4). A different approach was developed through a collaboration between Australia's CSIRO (Commonwealth Scientific and Research Organisation) and Fuel & Combustion Technology Pty Ltd (FCT) (Madsen & Scarlett, 1999; Manias *et al.*, 2000, 2001; Manias, 2008; Scarlett *et al.*, 2001). The aim of this work was to design, construct, install and commission an online PXRD analyser capable of continuously monitoring phase abundances for use in process-plant control (Dhanjal *et al.*, 2006). The cornerstone of this analyser was the use of an Inel CPS 120 curved detector that allowed the simultaneous collection of 120° in 2θ of diffraction data, enabling rapid data collection with no moving parts. This latter feature is very desirable in the environment of an operating plant. This instrument is currently marketed by a subsidiary of FCT (FCT AcTech) under the name 'COSMA', which is an acronym for Continuous On-Stream Mineral Analyser. This instrument takes a continuous stream from either the clinker plant or cement mill and provides full QPA *via* the Rietveld method every minute. The development of the Rietveld method for this automated analysis involved a detailed description of all of the component phases within the material to be analysed. In the case of minor phases, this involved their separation from the bulk specimen in order to fully define their crystallographic parameters (Madsen & Scarlett, 1999). Such a methodology is complex and time consuming, and is inappropriate for the rapid-turnaround requirements of an on-stream instrument. However, with a consistent product such as cement, the parameter set being refined may be closely restricted or even fixed based on these phase definitions and therefore rapidly applied without the risk of analytical instability. The accuracy of such a method is dependent on the consistency of the phase chemistry of the samples. If any of the material inputs to the process change dramatically, the method must be adjusted to accommodate the changes in phase parameters. Although this instrument was originally designed for the cement industry, such an approach could be applicable in a variety of mineralogical contexts in the mining and process industries.

7.7.4.2.3. *Energy-dispersive diffraction (EDD)*

Obtaining a representative sample is one of the most important issues affecting the outcome of process control. One approach to improving online sampling is the use of higher-energy, more penetrating radiation (O'Dwyer & Tickner, 2007, 2008). O'Dwyer and Tickner developed a prototype instrument incorporating polychromatic radiation rather than the traditional monochromatic beam associated with most laboratory instruments (O'Dwyer & Tickner, 2006). Diffraction data resulting from the use of polychromatic radiation are typically presented as a function of energy rather than of diffraction angle. The basis of this 'energy-dispersive diffraction' experiment is still the satisfaction of Bragg's law,

$$\lambda = 2d\sin\theta, \qquad (7.7.1)$$

where λ is the wavelength of the incident radiation, d is the interplanar spacing of the diffracting phase and 2θ is the diffraction angle. The energy of the incident radiation is related to its wavelength *via*

$$E_{\rm keV} = \left(\frac{hc}{\lambda}\right)6.24\times10^{25} = \frac{12.4}{\lambda}, \qquad (7.7.2)$$

where $E_{\rm keV}$ is the energy of the incident radiation in keV, h is Planck's constant (6.626068×10^{-34} J s^{-1}), c is the speed of light (2.998×10^{8} m s^{-1}) and λ is the wavelength associated with this energy in ångströms. Rearrangement and substitution into Bragg's law allows the expression of energy in terms of d and diffraction angle:

$$E_{\rm keV} = \frac{6.2}{(d\sin\theta)}. \qquad (7.7.3)$$

O'Dwyer and Tickner's instrument was coupled with a simple linear regression calculation that effectively operated as a single-

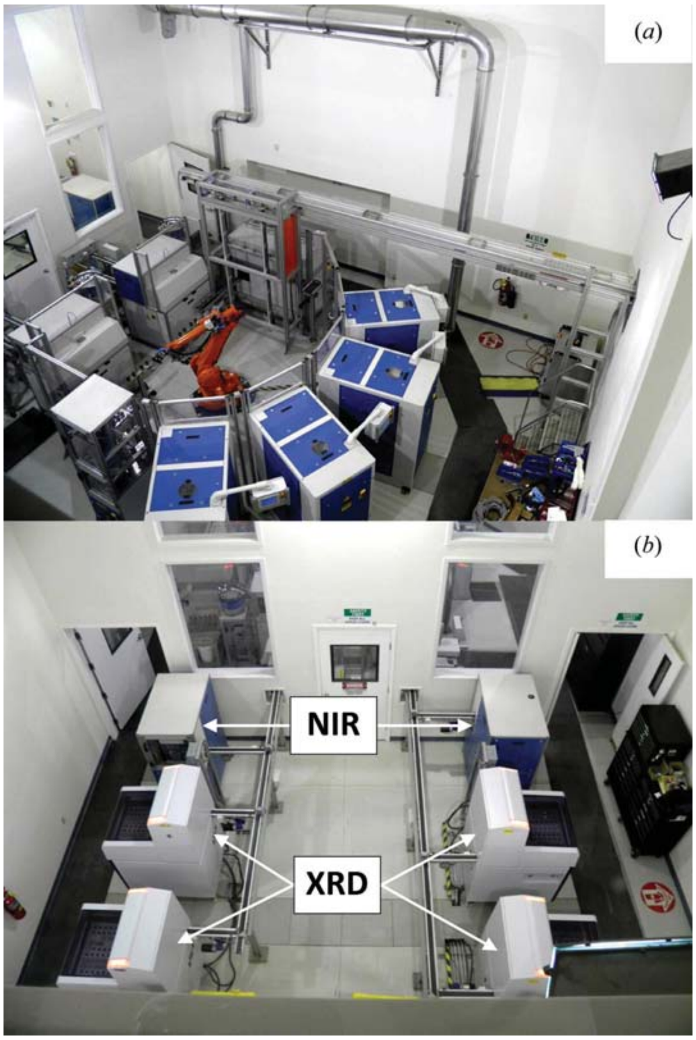

Figure 7.7.8

peak method for QPA, developed from a ‘training suite’ of samples (O’Dwyer & Tickner, 2007). This is a simple and rapid approach to data analysis for an in-plant environment. More recently, however, it has been shown that EDD data may be quantified directly using a Rietveld refinement technique (Scarlett *et al.*, 2009) that improves the accuracy and applicability of this instrument.

7.7.4.2.4. *Freeport–McMoRan automated PXRD–NIR mineralogy laboratory*

A fully automated PXRD–NIR (near-infrared) installation was commissioned in 2009 for the international mining company Freeport–McMoRan Copper and Gold Inc. (FCX). The installation consists of two parts. The first is the robotics sample-preparation area (Fig. 7.7.8*a*) and the second is the analytical area containing four Bruker D4 Endeavour PXRD instruments and two ASD NIR units in Herzog automation cabinets (Fig. 7.7.8*b*). The design capacity of the laboratory is 500 PXRD mineralogy and approximately 800 NIR clay and alteration mineral analyses per day, and the system handles sample material from all mine operations, including blast holes, geological samples and speciality materials. The PXRD units perform 10 min data collections followed by 10 min Rietveld QPA using automated batch processing. The final Rietveld fit for every sample is checked by a mineralogist or technician. Results are reported automatically *via* a laboratory information system (LIMS).

Automated systems such as this must be carefully monitored to ensure that they are performing as expected. To ensure this, standard materials are analysed daily [including NIST corundum, laboratory ore standard (granite) and a blank (glass) to check for contamination]. A minimum of 5% of samples are replicated, and the pulverizing mills are checked daily to ensure that the proper particle size is produced.

7.7.4.3. *Research*

7.7.4.3.1. *Structure solution*

QPA *via* the Rietveld method is most easily obtained when the crystal structures of all component phases are known. In addition to the amounts of the component phases, Rietveld analyses have the potential to provide a wealth of crystal chemical data on the solid phases in a sample. These are powerful data that can also shed light on the mineral provenance and its relationship to other species, which have implications for understanding the genesis, extent and purity of ore bodies. Many mineral species are incompletely described owing to a lack of single crystals of suitable quality for structural determination. Recent advances in powder-diffraction methodology facilitate crystal structure solution from powder data [*i.e.* simulated annealing (Coelho, 2000) and charge flipping (Coelho, 2007; Oszlányi & Sütő, 2004, 2008)]. Detailed methodologies for structure solution are given in Part 4 of this volume.

7.7.4.3.2. *Environment*

The impact of mining and mineral processing activities on public health and the environment has been an increasingly important consideration in recent times. The detrimental effects of mining may include the clearance of land, erosion, a reduction in biodiversity, the contamination of ground and surface water, air pollution and greenhouse-gas emissions. In an effort to address these effects, many countries have implemented codes to ensure the rehabilitation of land, after the cessation of mining/extraction activity, to its original state or to other uses such as agriculture, industrial or residential purposes. In fact, environmental aspects are now one of the most important factors in determining the economic viability of mining a particular ore body (Jambor, 1994). As in the exploration process, an understanding of the mineralogy of solid gangue, mine waste and drainage effluents is essential for understanding the behaviour of these materials and their potential environmental impacts. X-ray powder diffraction is an invaluable tool for the direct identification of such mineralogy and as an adjunct to other characterization techniques.

One of the greatest environmental issues faced by active and abandoned mines is that of acid mine drainage (AMD). AMD occurs as a result of the exposure of sulfide minerals to oxygen and water. The most common of these minerals are pyrite and marcasite (both polymorphs of FeS_2). Oxidation of these minerals produces sulfuric acid and the precipitation of a range of ochreous deposits. These precipitates are deposited in rivers and streams and, together with the low-pH conditions accompanying the sulfuric acid, they have an impact on aquatic life. The acidic run-off often contributes to surface water and groundwater, lowering its pH. The original sulfide minerals often contain numerous trace elements (*e.g.* Mn, Zn, Co, Ni and Cu for Fe, and As and Se for S) that are also released into the environment upon weathering. Evidence of such release and precipitation is still apparent from ancient workings as described by Davis *et al.* (2000) in their study of the Rio Tinto system in the province of Huelva, southwestern Spain. According to them, this system is 'one of the most polluted fluvial-estuarine systems in the world and most likely has been so for thousands of years'. Phenomena similar to AMD may also occur naturally through the oxidation of sulfide-bearing soils and rocks (Schwertmann *et al.*, 1995).

Much research has been directed towards understanding and addressing the effects of AMD and the nature and origin of the precipitates formed. Some examples follow.

(i) Mineral samples from an area in the Sokolov Basin, Czech Republic, were characterized by Murad and Rojík using a combination of PXRD and chemical methods (Murad & Rojík, 2005). They found that variations in mine-drainage precipitate mineralogy can serve as indicators of pH and sulfate conditions, possibly indicating the genetic environment during precipitate formation. They used this detailed study as a means of relating other properties such as colour (which may be used for rapid assessment in the field or remotely) to mineralogy.

(ii) PXRD was used to confirm the mineralogy of samples used in a study of the geochemistry of bacterially-induced mineralization of mine-drainage precipitates (Kawano & Tomita, 2001).

(iii) Jambor *et al.* (2007) used PXRD to determine quantitative mineralogy in order to compute the neutralization potential (NP) of a selection of sedimentary, metamorphic and igneous extrusive rocks. These results have been compared with those from the Sobek method of static testing (Sobek *et al.*, 1978) for predicting the potential for AMD. The two methods were found to be in moderate agreement.

(iv) *In situ* diffraction studies of the stability of mine waste during dehydration–hydration reactions have been conducted using a purpose-built stage and control system (Peterson & Grant, 2005) in order to determine the controlling factors.

(v) Jarosite is an iron sulfate mineral found in ochreous deposits resulting from AMD, and it contributes to acidic run-off and increased metal mobility in these environments. It also forms during bioleaching and may act as a kinetic barrier to further reaction. *In situ* diffraction studies into the nucleation and crystallization of jarosite have been conducted (Brand *et al.*, 2012; Scarlett *et al.*, 2013)

One of the major environmental concerns facing mining operations is their production of greenhouse gases. Carbon dioxide is the most prevalent of these anthropogenic contributions to the Earth's atmosphere and has increased globally by about 100 p.p.m. (36%) over the last 250 years from around 278 p.p.m. in 1750 to 390 p.p.m. in 2011 (Stocker *et al.*, 2013). This increase has not been linear and the growth rate of CO_2 in the atmosphere has increased dramatically in the past 30 years. An increase of 50 p.p.m. from the pre-industrial era (prior to AD 1750) baseline was measured in the 1970s, with a further increase of 50 p.p.m. in the next 30 years. Between 1995 and 2000, atmospheric CO_2 increased by about 19 p.p.m., which is the highest average growth rate ever recorded.

In 1995, Lackner and co-workers proposed a method for the disposal of atmospheric CO_2 *via* the formation of stable carbonate minerals (Lackner *et al.*, 1995). They considered high-temperature and aqueous processing and investigated a range of common rocks rich in magnesium or calcium as suitable raw materials. A potential method for the implementation of this CO_2 sequestration is *via* the dissolution of silicates and precipitation of carbonates in mine tailings (Wilson, Dipple *et al.*, 2009). Mine tailings are particularly suited to this purpose as they are generally milled, which increases their surface area and accelerates mineral–fluid interactions. To some extent, this process occurs naturally, as demonstrated by Wilson and co-workers regarding the trapping and storage of atmospheric CO_2 in tailings from historic chrysotile mines at Clinton Creek, Yukon Territory and Cassiar, British Columbia. They used QPA from PXRD data to determine the mineralogy of the tailings in order to estimate the amount of CO_2 trapped within fine-grained, hydrous carbonate minerals (Wilson, Raudsepp & Dipple, 2009). The use of PXRD allows the various carbonate minerals to be distinguished and has an advantage over scanning electron microscopy (SEM) methods in its applicability to fine-grained, intergrown or hydrous minerals that may be affected by the electron beam. These findings indicate that it may be beneficial to promote the formation of secondary carbonate minerals at active mines in order to reduce or offset their net greenhouse-gas emissions.

7.7.5. Conclusions

From exploration to market to reclamation, the mining industry is reliant on detailed mineralogical knowledge of the materials with which it deals. The location of ore bodies can be determined from knowledge of the mineralogy of the surrounding landscape. The mode of extraction of valuable minerals or metals is determined by the assemblages in which they occur. The ease of processing and the final properties of marketable products are dependent upon the crystal chemistry of the starting materials. At all stages of production, quality control may be based around knowledge of the mineralogy of the intermediate products. New processing routes and modes of environmental protection and remediation can be developed through detailed understanding of the crystal structural nature of the minerals participating in the various reactions. Ultimately, the environmental history of the Earth and other planets may be ascertained by analysis of their mineralogy.

The level of detail of a PXRD analysis may vary from the simple identification of individual minerals to extensive structural studies probing the fine details of crystal structure at the atomic level. One of the most useful PXRD techniques relevant to the minerals industry is that of quantitative phase analysis. This technique finds application throughout all aspects of mineral processing and is now a routine tool in the field, the plant and the laboratory. PXRD is a powerful tool in its own right, but is greatly enhanced by association with other analytical techniques. For example, bulk chemical analysis can assist greatly with phase identification, and microanalysis *via* electron-beam techniques can indicate levels of chemical substitution within minerals. The modern analytical laboratory has a powerful array of techniques for the characterization of mineralogical specimens, but at its heart PXRD is based directly upon the structural nature of crystalline materials, and as such is the most fundamental 'fingerprinting' technique for assessing mineral assemblages.

The authors wish to thank Arnt Kern (Bruker AXS) and Douglas Allen (FCX) for details of the PXRD–NIR automated mineralogy laboratory.

7.8. Ceramic materials

W. Wong-Ng

7.8.1. Introduction

7.8.1.1. *Definition*

The term 'ceramics' is derived from the Greek word *keramikos*, which means 'burnt stuff' (Musikant, 1991), and was used originally to describe ware made from clay. After forming objects in clay, one can shape the material and harden it by firing at high temperatures to produce a ceramic which is relatively strong, hard and less permeable to fluids.

In the USA an extension of the meaning of 'ceramic' was authorized by the American Ceramic Society in the 1920s; chemically, clay is a silicate and it was proposed that the term 'ceramic' should be applied to all the silicate industries. This extended definition brought in glass, vitreous enamel and hydraulic cement. By a natural extension, the term 'ceramic' has since embraced all products made from fired clay, *i.e.* bricks and tiles, pipes and fireclay refractories, sanitaryware and electrical porcelain, as well as pottery tableware. Nowadays, the definition has been developed further into a broader term, so as to include in general inorganic, nonmetallic materials made from compounds of a metal and a nonmetal. Ceramics may be crystalline, partly crystalline or amorphous. They are formed by the action of heat and subsequent cooling. Ceramic materials tend to be strong in compression, but weak in shearing and tension. They are stiff and brittle. Most ceramic materials can withstand the chemical erosion that occurs in an acidic or caustic environment, and are nonconductors of heat and electricity, but their properties vary widely.

Ceramic materials can be subdivided into traditional and advanced ceramics. Traditional ceramics include clay-based materials. Advanced ceramics are tailored to have premium properties through the application of advanced materials science and technology to control the composition and internal structure. Advanced ceramic technology is often cited as an enabling technology: it enables engineers to design and build advanced systems for applications in fields such as the aerospace and automotive industries, and in consumer electronics.

7.8.1.2. *A brief history of ceramic development*

For detailed historical surveys of ceramic materials, readers can refer to *Kirk-Othmer Encyclopedia of Chemical Technology* (2007) and *The Britannica Concise Encyclopedia* (1994–2008). We will summarize the development of ceramics into what Norton called 'cycles in ceramic history' (Norton, 1978).

Since the dawn of humanity, use has been made of the plastic properties of clay for creating sculptures of humans and animals (known as early as the Paleolithic period). However, the practice of firing clay objects to make them hard, waterproof and fireproof became widespread only in the Neolithic period (about 5000 BC). Mastering ceramic production was one of the most important achievements of primitive people: the cooking of food in clay vessels made it possible to expand the range of edibles. The history of ceramics can be divided into alternating periods of activity and dormancy. These periods are:

The pre-Christian era – Ceramic ware was made largely from native clays, which produced a soft earthenware. Hand moulding and wheel throwing were usual. Glazes containing lead and tin were commonly used with a variety of colours. During this period ceramics were used largely in the household, but art ware was also produced.

The first 17 centuries of the Christian era – A great variety of pottery was made nearly everywhere, but most of it was earthenware. A giant step in pottery development took place in China. Earthenware was gradually refined to stoneware and finally to white translucent porcelain. Porcelain was introduced to Europe during Marco Polo's time around the thirteenth century.

Eighteenth-century Europe – Significant effort was made to duplicate Chinese porcelain. Vitreous pottery produced on the continent continued to be largely a hard porcelain body made of a kaolin–feldspar–quartz mixture, bisque-fired at low temperature and gloss-fired at a high temperature.

The nineteenth century – Germany invented the continuous-chamber kiln, a principle that had been used in China many years earlier, and of which Europeans were unaware. Towards the end of the 19th century electric power enabled the use of much higher temperatures.

The twentieth century to 1930 – Powerful electric furnaces enabled the making of silicon carbide, fused alumina and fused magnesia. Other changes included the increased use of gas and oil for kiln fuel, the invention of tunnel kilns and the use of electric motors for powerful forming machines.

The period from 1925 to the 1970s – Great gains in understanding the theories behind ceramic science were made due to the integration of multidisciplinary fields and the developments of a number of processing tools (high-temperature furnaces with even temperature distribution, isostatic pressing, slip casting, roller forming), analytical tools (in particular, powder-diffraction techniques), precise measurements of temperature, availability of phase diagrams, and the establishment of many ceramics-related conferences for information exchange.

The period from the 1970s to the present – Traditional ceramics production continued, but there has been a giant step towards the development of fine/advanced ceramics for modern industrial applications.

7.8.1.3. *Industrial aspects of fine ceramics/advanced ceramics*

In the past several decades there has been a rapidly growing interest in what are called fine, advanced or engineering ceramic materials. The Japanese industry, recognizing the economic potential of high-tech materials, had a systematic plan (blueprint) to develop new/fine ceramics in order to further its lead in the post-industrial age (Musikant, 1991). Fig. 7.8.1 shows the various areas that have been chosen for focus by Japan in a condensed format. The three concentric rings (reading from the centre outward) give the functions, properties and applications. The function labelled 'electric, magnetic' represents Japan's huge electronics industry and all the application areas in electronic devices in which Japan has been quite successful in the post-World War II era. The 'mechanical' function is directed largely to the automotive area. In the applications ring, the 'tool and jigs' item also contributes to low costs in automotive production, as ceramic tools have permitted an order of magnitude increase in speed in cutting and machining.

The transition from traditional to fine ceramics was only made possible by controlling the micro/mesostructure of ceramics, which in turn could not have been successful without sophisticated analytical tools, including powder diffractometers and electron microscopes. Fine ceramics have outstanding electrical properties, optical properties, abrasion resistance, heat resistance and/or corrosion resistance. Nowadays many ceramic companies apply such features in developing environmentally friendly automobile engines and industrial machinery, as well as other products, contributing to the betterment of society.

7.8.2. Categories of ceramics

Today's ceramics cover a wide range of materials. There are several common classifications of ceramics, depending on their type, chemical constituents and functionality. Chemically, they can be classified as oxides and non-oxides. In terms of their functionality, they can be classified broadly into electronic ceramics and structural ceramics. This chapter attempts to roughly classify them in terms of both applications and material types, namely, as art and archaeological ceramics, and as modern technical ceramics, with much emphasis on the latter. Hosts of other ceramics are still in various stages of development and production. The classification is simply an indication of the range of applications and the ceramic materials available.

7.8.2.1. *Art and archaeological ceramics*

Ceramics are known to laymen as the objects or the art that deals with the design and fabrication from dried clay. All types of earthenware, stoneware and porcelain are included in the term 'art ceramics'. Porcelain refers to wares that are fired at high temperatures and are to some extent translucent, while stoneware and earthenware (such as terracotta) are fired at lower temperatures and are opaque. The development of artistic ceramics involves the selection of clay and admixtures that make up the ceramic mass, the methods used to shape and fire the mass, and the methods used to treat and decorate the surface of the art work.

Ceramic artifacts, which are among the most common artifacts to be found at archaeological sites, play an important role in understanding the culture, technology and behaviour of people of the past. These artifacts are generally found in the form of small fragments of broken pottery called shards (or sherds). Processing of collected shards includes two main types of analysis: traditional and technical. Traditional analysis involves sorting ceramic artifacts, shards and larger fragments into specific types based on style, composition, manufacturing and morphology. The technical approach involves an examination of the phases and composition of ceramic artifacts and shards to determine the source of the material and the possible manufacturing site. Common techniques include powder X-ray diffraction and microscopic examinations.

7.8.2.2. *Modern technical ceramics*

Technical ceramics are categorized according to their modern usage, properties and applications:

7.8.2.2.1. *White ware*

White ware is a class of products that includes electrical and chemical technical porcelains and chinaware, and commonly used products such as fine dinnerware, wall tiles, pottery, dental porcelain and sanitary ware (Jones & Berard, 1993). White ware is usually manufactured from a mixture of minerals consisting of special clays, fluxing minerals (often feldspars) and finely ground quartz (SiO_2). This mineral mixture is shaped and then vitrified at high temperatures to produce a dense, hard material. An important step in the manufacturing of most white-ware products is the application of a glassy coating, called a glaze, to the product so as to seal the surface of the ceramic to prevent absorption of liquids and to increase the aesthetic appeal. Porcelain enamels are glassy coatings fused onto metals to provide corrosion protection and decoration. The fired colour is often white; hence the origin of the term 'white ware'.

7.8.2.2.2. *Structural clay products/building and construction materials (Jones & Berard, 1993)*

The structural clay products industry is concerned with the manufacture of bricks, construction tiles, floor tiles, vitrified sewer pipes, drain tiles *etc*. These products are usually manufactured from local natural mineral deposits such as shales, which are mineral mixtures rich in clays but with impurities. Durability and strength at low cost are keys to the success of these ceramic structural products.

The cement and gypsum industries are concerned with the production of the cements and plasters used in concrete, wallboards and other construction materials. They are produced by heat treatment of crushed raw materials to render them reactive with water to form a stone-like mass. In the cement industry, heat treatment is carried out in large rotary kilns. The major raw materials for the manufacture of cement are limestone, clays and aluminium-bearing minerials. Iron- and magnesium-bearing phases may also be present. Plaster is produced by gentle heating of gypsum ($CaSO_4{\cdot}2H_2O$) to drive off part of the natural chemical water.

7.8.2.2.3. *Machinery (Musikant, 1991)*

The ceramic applications in machinery are extremely demanding (Richerson, 1982). Heat-resistant structural materials such as Si_3N_4, SiC, cordierite ($2MgO{\cdot}2Al_2O_3{\cdot}5SiO_2$), mullite ($3Al_2O_3{\cdot}2SiO_2$) and ZrO_2 have found their way into ceramic machinery applications. Ceramic heat-engine components include internal parts of diesel engines, turbine blades, high-temperature bearings, external-combustion-engine components and ceramic heat exchangers. Other machinery applications include high-temperature transport rollers, and high-temperature gas and molten metal transport pipes.

Some ceramic parts can be fabricated to net shape or near net shape by appropriate densification methods. However, machining of some of the surfaces is required to meet dimensional tolerances, to achieve an improved surface finish or to remove surface flaws. Ceramic materials are often difficult and expensive to machine because of their high hardness and brittle nature. Machining must be done carefully to avoid brittle fracture of the component and the tool used must have a higher hardness than the ceramic being machined.

7.8.2.2.4. *Cutting tools*

Quality cutting tools must possess three characteristics: (1) high hardness and strength at high temperatures, (2) sufficient toughness (so that tools do not chip or fracture) and (3) high wear resistance to ensure long tool life (Schneider, 2009). The characteristics of modern ceramic cutting tools are a consequence of the intrinsic properties of the ceramics: high hardness at room and elevated temperature, high strength in compression, good chemical stability at high operating temperatures, and high thermal conductivity, which helps to reduce tip temperature. Cutting-tool materials have been improved with the introduction of Si_3N_4-based ceramics, SiC whisker-reinforced Al_2O_3, dense Al_2O_3–TiC materials, $Al_2O_3{\cdot}TiC$ and transformation-toughened ZrO_2 (discussed later in Section 7.8.3.3.4). Other examples of modern ceramics for cutting-tool applications are TiC, TiC·TiN, Si_3N_4, SiAlON, TiN cermet, cubic BN, WC coated with TiC, TiN, cubic BN and synthetic diamond.

7.8.2.2.5. *Nuclear applications (Musikant, 1991)*

The fission reactor consists of fissionable fuel, moderators that control the rate of fusion by absorbing neutrons and reflectors that minimize escape of neutrons out of the reactor. Nuclear fuel is a material that can be 'burned' by nuclear fission or fusion to derive nuclear energy. Most nuclear fuels contain heavy elements that are capable of nuclear fission. When these fuels are struck by neutrons, the nuclei of the heavy elements break apart, emitting more neutrons. The most common fissile nuclear fuels are uranium-235 (^{235}U) and plutonium-239 (^{239}Pu). For fission reactors, the fuel is usually based on the metal oxide (UO_2). Uranium nitride and carbide fuels have the advantages of higher heat conductivities and melting points. Because of the absence of oxygen in uranium carbide fuel as well as the ability to accommodate a ceramic coating (a ceramic–ceramic interface has structural and chemical advantages), uranium carbide is an ideal fuel candidate for certain gas-cooled fast reactors. Another essential element of the nuclear reactor is shielding. The shield prevents neutrons as well as gamma rays produced during the fission process from escaping into the environment. The various requirements of the shield can be met by the use of alternating layers, usually within a massive concrete structure. Some of the advanced ceramics useful for helping to provide these functions include reactor components (SiC, B_4C and Al_2O_3) and dosimeters (CaF_2, K_2SO_4, LiF).

7.8.2.2.6. *Electronic ceramics*

There are literally thousands of applications of advanced ceramics that depend on the interaction of the ceramics with applied electric or magnetic fields. While electronic properties are the main focus in these materials, in many cases additional mechanical- and thermal-property requirements must be met. We select 13 popular ceramic materials or applications for illustration.

7.8.2.2.6.1. Batteries and fuel cells

Two galvanic applications of conductive ceramics are in batteries and fuel cells (Jones *et al.*, 2012; Kordesch & Simader, 1996). A battery is a device that converts chemical energy into electricity. In its simplest form it consists of two metal or metal-oxide elements, called the anode and the cathode, immersed in a liquid or solid chemical compound called the electrolyte. Ion flow in the electrolyte is accompanied by a compensating movement of electrons from the anode; the electrons flow through an appropriate conductor to the cathode, and the electric circuit is complete. Batteries are abundant in modern life, especially finding use in portable appliances and motor vehicles. High-energy-density batteries based on sodium β-alumina have been developed for vehicular applications. β-Alumina has the formula $Na_2O{\cdot}11Al_2O_3$ and has a complicated structure consisting of spinel blocks sandwiching conduction planes in which Na^+ can rapidly migrate. A related structure is β''-alumina, $Na_2MgAl_{10}O_{17}$, where Mg^{2+} ions stabilize the structure and require additional Na^+ ions in the conduction plane for charge compensation. It is used as the solid electrolyte in the sodium–sulfur storage battery.

Fuel cells produce electric power in a similar way to a battery, except that power production is prolonged by supplying a gaseous or liquid fuel to the anode and air or oxygen to the cathode. Fuel cells have been developed for load-levelling in electric power plants, but they also may be used in motor vehicles. Of the several fuel-cell types, ceramics play key roles in the molten carbonate fuel cell (MCFC) and the solid oxide fuel cell (SOFC). In the MCFC, nickel-oxide ceramics serve as porous anodes for the molten salt (carbonate) electrolyte. In SOFCs, ceramics serve not only as the solid electrolyte (such as ZrO_2) but also as anodes and as conductive connections between adjacent cells (cobaltites, manganites and chromites of various transition metals).

7.8.2.2.6.2. Ceramic capacitors

Capacitors act as electrical buffers, diverting spurious electric signals and storing surges of charge that could damage circuits and disrupt their operation (Buchanan, 1986). A ceramic capacitor is a fixed capacitor with the ceramic material acting as the dielectric. It is constructed of two or more alternating layers of ceramic and a metal layer acting as the electrodes. The composition of the ceramic material defines the electrical behaviour and therefore the application of the capacitors, which are divided into several stability classes. Class-1 ceramic capacitors have high stability and low losses for resonant circuit applications. Examples are $MgNb_2O_6$, $MgTa_2O_6$, $ZnTa_2O_6$, $(ZnMg)TiO_3$, $(ZrSn)TiO_4$ and $Ba_2Ti_9O_{20}$. They have the lowest volumetric efficiency of the different types of ceramic capacitors. This is the result of the relatively low permittivity values (6 to 200 $\mathrm{F\,m^{-1}}$). Class-2 ceramic capacitors have high volumetric efficiency for buffer, by-pass and coupling applications. These are capacitors which have a dielectric with a high permittivity and therefore a better volumetric efficiency than class-1 capacitors, but lower reliability and stability. Class-3 barrier layer or semiconductive ceramic capacitors are capacitors which have a dielectric with a very high permittivity and therefore a better volumetric efficiency than class-2 capacitors. However, class-3 capacitors have poorer electrical characteristics, lower reliability and lower stability than class-2 capacitors. Barrier-layer ceramic capacitors are made of doped ferroelectric materials such as barium titanate ($BaTiO_3$).

7.8.2.2.6.3. High-temperature ceramic superconductors

High-temperature ceramic superconductors (abbreviated HTSs) are ceramic materials that behave as superconductors at unusually high temperatures. The first high-T_c superconductor was discovered in 1986 by IBM researchers Karl Müller and Johannes Bednorz (Bednorz & Müller, 1986), who were awarded the 1987 Nobel Prize in Physics 'for their important breakthrough in the discovery of superconductivity in ceramic materials' (Ford & Saunders, 2005). HTSs are type-II superconductors, and allow magnetic fields to penetrate their interior in quantized units of flux. The layered structure also gives a directional dependence to the magnetic field response. Whereas metallic superconductors usually have transition temperatures below 30 K, HTSs have been observed with transition temperatures as high as 160 K. The most studied high-temperature superconductors are the cuprate superconductors including yttrium barium copper oxide ($Ba_2YCu_3O_7$, famous as the first material to achieve superconductivity above the boiling point of liquid nitrogen), and $(Bi,Pb)_2Sr_2Ca_2Cu_3O_{10}$. Other high-$T_c$ cuprate superconductors include $La_{1.85}Ba_{0.15}CuO_4$, $HgBa_2Ca_2Cu_3O_x$ and $Ba_2RCu_3O_7$ (R = a lanthanide). The compound MgB_2 is also generally included with high-T_c materials. In recent years, a number of iron-based compounds [the iron pnictides SmFeAs(O,F), CeFeAs(O,F), LaFeAs(O,F)] have also been found to be superconducting at relatively high temperatures.

Two decades of intense experimental and theoretical research, with over 100 000 published papers on the subject, have reported many common features in the properties of high-temperature superconductors (Leggett, 2006), but so far there is no universally accepted theory to explain their properties. Ceramic superconductors and other unconventional superconductors differ in many important ways from conventional superconductors, such as elemental mercury or lead, which are adequately explained by the Bardeen–Cooper–Schrieffer (BCS) theory.

7.8.2.2.6.4. Ferroelectric ceramics

Ferroelectric materials belong to a subclass of pyroelectric materials. All ferroelectric materials are pyroelectric; however, not all pyroelectric materials are ferroelectric. Below a transition temperature called the Curie temperature, ferroelectric and pyroelectric materials are polar and possess a spontaneous polarization or electric dipole moment. This polarity can be reoriented or reversed fully or in part through the application of an electric field with ferroelectric materials. The direction of the spontaneous polarization conforms to the crystal symmetry of the material, while the reorientation of the spontaneous polarization is a result of atomic displacements. The magnitude of the spontaneous polarization is greatest at temperatures well below the Curie temperature and approaches zero as the Curie temperature is approached.

The phenomenon of ferroelectricity was discovered by J. Valasek (1921), who was investigating the dielectric properties of Rochelle salt ($NaKC_4H_4O_6{\cdot}4H_2O$). Barium titanate ($BaTiO_3$) was discovered to be ferroelectric in 1944 by von Hippel (1950) and is the most commonly encountered ferroelectric material. While there are over 250 materials that exhibit ferroelectric properties, some of the more common/significant materials include lead titanate, $PbTiO_3$, lead zirconate titanate (PZT) and lead lanthanum zirconate titanate (PLZT). Applications for ferroelectric materials include capacitors, non-volatile memory, piezoelectrics for ultrasound imaging and actuators, electro-optic materials for data-storage applications, thermistors, switches, oscillators and filters, and light deflectors, modulators and displays.

7.8.2.2.6.5. Glass ceramics

Glass ceramics are polycrystalline materials produced through crystallization of base glass (Montedo *et al.*, 2012). Glass ceramics are mostly produced in two steps, or what is referred to as a 'controlled crystallization' process: the glass is cooled and is then reheated in a second step, resulting in partial crystallization. These materials share many properties with both glasses and ceramics. Glass ceramics have an amorphous phase and one or more crystalline phases. They usually have between 30 to 90% crystallinity and yield an array of materials with interesting properties. A given glass ceramic may possess one or more of the following properties: zero porosity, high strength, toughness, translucency or opacity, pigmentation, opalescence, low or even negative thermal expansion, high temperature stability, fluorescence, machinability, ferromagnetism, high chemical durability, biocompatibility, bio-activity, ion conductivity, superconductivity, electrical isolation capabilities, low dielectric constant and loss, high resistivity, and high breakdown voltage. These properties can be tailored by controlling the base glass composition and by controlled heat treatment/crystallization of base glass. Considerable effort has been spent to obtain high-performance glass ceramics for potential applications in the medical, automotive and telecommunication applications (see Chapter 7.9).

7.8.2.2.6.6. Integrated-circuit packaging and substrates

In electronics manufacturing, integrated-circuit packaging is the final stage of semiconductor device fabrication, in which the small block of semiconducting material is encased in a supporting case that prevents physical damage and corrosion. The case, known as a 'package', supports the electrical contacts that connect the device to a circuit board. The earliest integrated circuits were packaged in ceramic flat packs (flat package): a rectangular or square package with leads parallel to base plane attached on two opposing sides of the package periphery. Flat packages were made of glass, ceramic and metal, and they could provide hermetic packaging for circuits, protecting them from moisture and corrosion; the military used them for many years because of their reliability and small size. In the area of commercial packaging, a ceramic pin-grid array (a ceramic substrate with pins arranged in a pin-grid array) is a type of packaging used for integrated circuits. Integrated circuits have also been developed for sensor applications in medical implants or other bioelectronic devices. In such biogenic environments, sealing strategies have to be planned to avoid corrosion or biogradation of the exposed semiconductor materials. As one of the few materials well established in complementary metal-oxide semiconductor (CMOS) technology, titanium nitride (TiN) has been found to be exceptionally stable and well suited for electrode applications in medical implants (Hämmerle *et al.*, 2002; Birkholz *et al.*, 2010).

7.8.2.2.6.7. Magnetic ceramics

Magnetic ceramics, or ferrites, are a very well established group of magnetic materials (Valenzuela, 1994; *Kirk-Othmer Encyclopedia of Chemical Technology*, 2007). They have the general chemical formula $M(\mathrm{Fe}_x\mathrm{O}_y)$, M representing metallic elements other than iron. Ferrites are complex materials because they combine two complex attributes: ceramic microstructure and ferromagnetism. Ceramic microstructure is formed as a result of physical-chemical processes such as solid-state sintering.

Commercially prepared magnetic ceramics are used in a variety of permanent magnet, transformer, telecommunications and information-recording applications. Many new and exciting applications, theories and preparation technologies are still under development. Three basic classes of ferrites are made into magnetic ceramic products: spinels, hexagonal ferrites and garnets. Spinels have the formula $M(\mathrm{Fe}_2\mathrm{O}_4)$, where M is usually a divalent cation such as Mn^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+}, Cu^{2+} or Mg^{2+}. Because spinels are often cubic in structure, with no preferred direction of magnetization, they are 'soft' magnetically. The hexagonal ferrites have the formula $M(\mathrm{Fe}_{12}\mathrm{O}_{19})$, where M is usually Ba, Sr or Pb. The hexagonal crystal structure is complex, with a unique c axis. This is the easy axis of magnetization in the basic structure. Because the direction of magnetization cannot be changed easily to another axis, hexagonal ferrites are referred to as 'hard'. Garnet ferrites have the structure of the silicate mineral garnet and the chemical formula $M_3(\mathrm{Fe}_5\mathrm{O}_{12})$, where M is yttrium or a rare-earth ion. The garnet structure has tetrahedral, octahedral and dodecahedral (12-coordinated) sites. The net ferrimagnetism is thus a complex result of antiparallel spin alignments among the three types of sites. Garnets are also magnetically 'hard'.

7.8.2.2.6.8. Microwave communication ceramics

The recent progress in microwave telecommunication, satellite broadcasting and intelligent transport systems (ITSs) has resulted in an increasing demand for dielectric resonators (DRs), which are low-loss ceramic pucks used mainly in wireless communication devices (Fig. 7.8.2). Dielectric ceramics are commercially important as enabling materials for resonators, filters and other components in microwave communication systems (Sebastian, 2008; Vanderah, 2002). These ceramics have revolutionized the microwave wireless communication industry by reducing the size and cost of filter, oscillator and antenna components. The key properties required for a DR are high quality factor (Q), high relative permittivity and near zero temperature coefficient of resonance frequency, which are difficult to achieve simultaneously in a single material. Cohen (1968) performed the first extensive theoretical and experimental evolution of DRs using rutile ceramics (TiO_2) as the first microwave filter. The real breakthrough occurred in early 1970s when the first temperature-stable, low-loss $\mathrm{BaTi_4O_9}$ ceramics were developed by Masse *et al.* (1971). Later, $\mathrm{Ba_2Ti_9O_{20}}$ with improved performance was reported by Bell Laboratories (Plourde *et al.*, 1975). Extensive theoretical and experimental work followed. However, still only a limited number of useful dielectric ceramic materials are available. Today only two ceramic materials are optimized for 900-MHz-based station applications, one based on $\mathrm{ZrTiO_4}$ and the other based on $\mathrm{CaTiO_3}$–$\mathrm{NdAlO_3}$. For 2 GHz and higher, only the tantalite $\mathrm{Ba_3ZnTa_2O_8}$ has the required low dielectric loss. Many recent studies have been centred around pervoskites and pervoskite-like materials. The electronics industry is still searching for affordable new materials.

Dielectric resonators used in cellular base stations to store and transmit signals to handheld devices such as cell phones (Vanderah, 2002). Reproduced with permission from TCI Ceramics/National Magnetics Group.

7.8.2.2.6.9. Piezoelectric ceramics

The word piezoelectricity is derived from Greek, and means electricity resulting from pressure. Piezoelectricity was discovered in 1880 by French physicists Jacques and Pierre Curie (Curie & Curie, 1880). The piezoelectric effect is a reversible process and is understood as the linear electromechanical interaction between the mechanical and the electrical state in crystalline materials with no inversion symmetry. It has useful applications such as in the production and detection of sound, in the generation of high voltages, in electronic frequency generation, in microbalances, in ultrafine focusing of optical assemblies, and in fuel injector components.

The families of ceramics with pervoskite or tungsten-bronze structures that exhibit piezoelectricity include $\mathrm{BaTiO_3}$, $\mathrm{PbTiO_3}$, $\mathrm{Pb(Zr}_x\mathrm{Ti}_{1-x})\mathrm{O}_3$, $0 \le x \le 1$ (PZT), $\mathrm{KNbO_3}$, $\mathrm{LiNbO_3}$, $\mathrm{LiTaO_3}$, $\mathrm{Na_2WO_3}$, $\mathrm{Ba_2NaNb_5O_5}$, $\mathrm{Pb_2KNb_5O_{15}}$ and ZnO. More recently, there is growing concern regarding the toxicity of lead-containing devices. As a result, there is intense interest in non-lead-containing materials (Saito *et al.*, 2004), including $\mathrm{(K,Na)NbO_3}$ (with properties close to that of PZT), $\mathrm{BiFeO_3}$, $\mathrm{NaNbO_3}$, $\mathrm{Ba_4Ti_3O_{12}}$ and $\mathrm{Na_{0.5}Bi_{0.5}TiO_3}$.

7.8.2.2.6.10. Photovoltaics (solar cells)

The earth benefits from an impressive 125 000 TW of incident solar energy (Kippelen, 2007). While the future energy needs of the planet will likely be met with a combination of technologies, many believe that solar [in the form of photovoltaic (PV) cells] is the most efficient renewable energy source with the capacity to make a significant impact on global energy production. As a result, the race is on to push the performance of PV cells to a level where the total cost of the electricity generated is cheaper than that from carbon-based sources.

Most of the effort in PV cell fabrication is centred on thin-film deposition, rather than using wafer-based modules, as it uses less material and is much faster and simpler than the complex process of slicing, dicing and placing of silicon wafers. Manufacturers continue to experiment with various materials and refinements of the thin-film deposition process for solar cells based on silicon and other materials. The direct band-gap ceramic semiconductors cadmium telluride (CdTe), copper indium diselenide ($CuInSe_2$) and copper indium gallium diselenide alloy $Cu(InGa)Se_2$ have high optical absorption coefficients ($>10^5$ cm^{-1}) and are now emerging as the popular materials for the photoabsorption layer in thin-film photovoltaic (TFPV) cells. More than a dozen companies worldwide are already actively producing these cells.

7.8.2.2.6.11. Thermoelectric ceramics

The thermoelectric effect is the direct conversion of temperature differences to electric voltage and *vice versa*. A thermoelectric device creates a voltage when there is a different temperature on each side. Conversely, when a voltage is applied to it, it creates a temperature difference. These phenomena are known more specifically as the Seebeck effect (converting temperature difference to current), the Peltier effect (converting current to temperature difference) and the Thomson effect (conductor heating/cooling). The efficiency and performance of thermoelectric energy conversion or cooling is related to the dimensionless figure of merit (ZT) of the thermoelectric (TE) materials, given by $ZT = S^2\sigma T/\kappa$, where T is the absolute mean temperature, S is the Seebeck coefficient or thermoelectric power, σ is the electrical conductivity and κ is the thermal conductivity. Optimization of ZT is not a straightforward process because S, σ and κ are interrelated. Recent reports that relatively high ZT values (>1) are possible in both thin-film and bulk forms have revitalized interest in thermoelectric materials development (Tritt, 1996).

The stability of thermoelectric oxides at high temperature, their nontoxicity and their high oxidation resistance have made them highly relevant to waste-heat conversion applications. The low-dimensional cobaltates that include $NaCoO_x$, $Ca_2Co_3O_6$ and $Ca_3Co_4O_9$ (Shikano & Funahashi, 2003) exhibit the coexistence of large Seebeck coefficients and relatively low thermal conductivity. Consequently, considerable research has been conducted on thermoelectric oxides. Other examples being studied are $LaCoO_3$, $SrTiO_3$, Nb-doped $SrTiO_3$, $Zn_{0.98}M_{0.02}O$ (M = Ga, In, Al), the modulated layered cobalt oxides $Bi_2M_3Co_2O_8$ (M = Sr, Ca and Ba) and the Ruddleson–Popper phase $(SrTiO_3)_n(SrO)_m$ (Rowe, 2006). Research on thermoelectric oxide materials is ongoing, particularly in the nanostructured materials regime where simultaneous control of both the electric and phonon systems is important (Rowe, 2006).

7.8.2.2.6.12. Ceramic sensors

A sensor is a 'sensor element' including its physical packaging and external connections. A sensor element is a material or 'the fundamental transduction mechanism' that converts one form of energy into another. Some sensors may incorporate more than one sensor element (Buchanan, 1986; Smith, 2005). The terms sensor and transducer are often used synonymously. A transducer is a device that provides a usable output in response to a specified measurand, in which the measurand can be any physical, chemical or biological property or condition to be measured, and a usable output can be an optical, electronic or mechanical signal. Each sensor is different depending on its application. Oxide ceramics exhibit a number of special characteristics that make them particularly attractive for sensor applications. These include sensitivity to oxidizing and reducing gases or to temperature excursions. The following is a brief description of four types of sensors.

Physical sensors are materials that change their state and properties in a particular way while they are sensing physical changes. These includes changes in temperature, strain, force, pressure, displacement, position, velocity, acceleration, optical radiation, sound, flow rate, viscosity and electromagnetic fields. Three types of materials are in use: piezoelectric polymers, ceramics and composites. Piezoelectric sensors (quartz, ZnO, non-lead-containing piezoelectric materials) are used for applications including medical, aerospace, nuclear instrumentation and the automotive industry. Chemical sensors are used for the following measurands: ion concentration, chemical composition, rate of reactions, reduction–oxidation potentials and gas concentration. Application areas include the chemical-processing and fossil-fuel industries, and various environmental applications. Biosensors are sensors that respond to biologically produced substances, for example glucose, hormones and enzymes. Biological sensors are mainly of interest in health care and form an emerging trend in the diagnostic technology. Finally, thermistors, or thermally sensitive resistors, are electric resistors whose resistive properties vary with temperature. They are made of materials that have high temperature coefficients of resistance, where the temperature coefficient of resistance (TCR) of a material quantifies its change in resistance with temperature. Negative TCR, or NTCR, ceramics are materials whose electric resistance decreases as temperatures rise. These ceramics are usually spinel-based oxides of iron, cobalt and manganese that exhibit small-polaron conduction. NTCR thermistors are used as temperature sensors and as temperature-compensation resistors.

7.8.2.2.6.13. Ceramic varistors

A varistor is an electronic component with a 'diode-like' nonlinear current–voltage characteristic. The function of a varistor is to conduct significantly increased current when the voltage is excessive. Therefore, varistors are often used to protect circuits against excessive transient voltages by incorporating them into the circuit: when triggered, they will shunt the current created by the high voltage away from sensitive components.

Varistors are also known as voltage-dependent resistors. The most common type of varistor is the metal-oxide varistor (MOV). This contains a ceramic mass of zinc-oxide grains, in a matrix of other metal oxides (such as small amounts of bismuth, cobalt or manganese) sandwiched between two metal electrodes. The boundary between each grain and its neighbour forms a diode junction, which allows current to flow in one direction. The mass of randomly oriented grains is electrically equivalent to a network of back-to-back diode pairs, each pair in parallel with many other pairs. When a small or moderate voltage is applied across the electrodes, only a small current flows, which is caused by reverse leakage through the diode junctions.

7.8.2.2.7. *Optical ceramics or photonic ceramics*

Wide band-gap ceramic materials are transparent to light in the range of wavelengths near to or including the visible range, provided that they do not contain inhomogeneities, which can serve as scattering sites and which will reduce the transparency. Many ceramic materials, including single crystals, pore-free glasses and even pore-free single-phase polycrystalline ceramics, have found use as optically transparent materials in various forms from bulk solid-state components to high-surface-area forms such as thin films, coatings and fibres. The word 'photonics' is used to describe the collective optical properties of materials and the application of these properties to make useful devices. Such devices have found widespread use in the electro-optical field including: optical fibres for guided lightwave transmission, optical switches, laser amplifiers and lenses, hosts for solid-state lasers and optical window materials for gas lasers, and infrared (IR) heat-seeking devices for missile guidance systems and IR night vision.

Examples of optical materials can be divided into three areas, namely, transparent windows (Al_2O_3, MgF_2, ZnSe), mirror substrates (SiC and glass-ceramic Zerodur), and electro-optic materials (KH_2PO_4, $Ba_2NaNb_5O_{15}$ and $LiNbO_6$) (Musikant, 1991; Jones & Berard, 1993). Transparent polycrystalline electro-optic materials, such as PLZT ceramics, can be used for a variety of devices. An important photonic application of glass occurs in optical fibres that can carry a beam of light from one point to another without appreciable attenuation due either to absorption or to escape from the sides of the fibre. Lasers are devices capable of producing highly energetic beams of light having all waves in phase and of the same wavelength. These lasers are often made from specially doped glasses or single crystals such as Cr-doped Al_2O_3 (ruby lasers) or Nd-doped yttrium aluminium garnet (YAG lasers).

7.8.2.2.8. *Refractory ceramics*

Refractories are ceramic products manufactured for the purpose of withstanding the high-temperature corrosive conditions encountered in industrial furnaces and processing vessels. Refractories must have high melting temperatures, great strength, and resistance to heat, chemical attack and abrasive environments. Therefore refractories can be used in a furnace lining or other locations where they will be exposed to severe heating (Jones & Berard, 1993; McColm, 1983; Weimer, 1977).

Some examples of refractory materials are fireclay, silica, magnesite, chrome-magnesite, sintered alumina, beryllia, refractory cement, refractory coating and refractory concrete. Many of the metal carbide, nitride, silicide and boride materials are of considerable interest for structural and electronics applications because of their unique properties, including wear resistance (*e.g.* WC), high-temperature oxidation resistance (*e.g.* SiC and Si_3N_4), high hardness (*e.g.* B_4C), high toughness (*e.g.* Si_3N_4), resistance to attack by molten metals and glasses (*e.g.*TiB_2, BN and AlN) and unique combinations of properties such as high thermal conductivity/electrical insulation (*e.g.* AlN). Their structural applications have included heat-engine components, wear components, armour, corrosion-resistant crucibles (TiN_x, ZrN_x, HfN_x), cores of fuel elements of nuclear reactors (UC_x, ThC_x), high-temperature soldering (Mo_2C), protective coatings for rocket components, gas turbine blades (TiC_x) and high-temperature burners.

7.8.2.2.9. *Medical and bioceramics*

Today, advanced ceramics also find their way into the fields of medical and bioengineering. Prior to 1925, the materials used in implant surgery were primarily relatively pure metals. The 1930s marked the beginning of an era of better surgical techniques and also the first use of alloys such as Vitallium (Jones & Berard, 1993). In 1969 Hench (1991) and others discovered that various kinds of glasses and ceramics could bond to living bone (Hench, 1991; Yamamuro *et al.*, 1990). The final product was a new material which Hench called bioglass. This work inspired a new field called bioceramics.

Bioceramics and bioglasses are ceramic materials that are biocompatible. They are not the same as porcelain-type ceramic materials, but are closely related to either the body's own materials, or are extremely durable metal oxides that are inert in the body; at the other extreme are resorbable materials, which are eventually replaced by the materials which they were used to repair. Bioinert materials are non-toxic and non-inflammatory. These materials must be long lasting, resistant to structural failure and corrosion resistant; additionally, they must have a low Young's modulus to help prevent cracking of the material. Bioceramics are used in many types of medical procedures. There are in general two popular areas: the first area includes bone replacement/implants (Fig. 7.8.3 shows a titanium hip prosthesis, with a ceramic head and polyethylene acetabular cup), artificial joints (joint replacements are commonly coated with bioceramic materials to reduce wear and inflammatory response) and tooth implants. Common materials being used are Al_2O_3 (for implantation, wear surfaces) and hydroxylapatite (for bone material). A second area of application is as separators for biological components. Other examples of medical uses for bioceramics are in pacemakers, kidney dialysis machines and respirators (Kassinger, 2003). One potential use for bioceramics includes the treatment of cancer through the dispersion of drug-infused nanoparticles.

7.8.3. Applications of powder X-ray diffraction to the studies of ceramics

Applications of powder diffraction (using laboratory or synchrotron X-rays, neutrons or electrons) to the studies of selected categories of ceramics as listed above will be described according to the most relevant topics as listed in the three areas below. The general categories of subjects that are related to using powder diffraction in all categories of ceramics are:

(1) Phase characterization [phase identification; quantitative analysis; phase equilibria, crystal chemistry and crystal-

lography; phase evolution (films and bulk); phase transformation];

(2) Structure and microstructures (crystal structure; crystallite size; defects; residual stress measurements of ceramic components; texture/preferred orientation; thickness and roughness of ceramic films);

(3) Processing and performance (sintering/densification/grain growth; reaction mechanisms/sequence; kinetics and reaction rate; transformation toughening; degradation/corrosion of ceramics; crystallization of glass ceramics; microstructure evolution; and bulk modulus/compressibility determinations).

7.8.3.1. *Phase characterization*

7.8.3.1.1. *Phase identification*

Powder diffraction is a nondestructive technique that provides detailed information ranging from the phase identity to the detailed atomic structure of crystalline substances. It is a powerful tool in phase identification at various stages of ceramic manufacture, starting with the raw materials used to make ceramics, to advanced ceramic products. Many useful sources of information about diffraction theory and interpretation applied specifically to powder methods are available (Klug & Alexander, 1974; Cullity, 1978; Bish & Post, 1989; Zevin & Kimmel, 1995; Moore & Reynolds, 1997; Jenkins & Snyder, 1996; Cullity & Stock, 2001; Pecharsky & Zavalij, 2008; Clearfield *et al.*, 2008; Dinnebier & Billinge, 2008; Mittemeijer & Welzel, 2013). For most samples, the aim of the analysis is to identify the crystalline phases present. Even when other information is sought (*e.g.*, unit-cell calculations, quantitative determinations *etc.*), identification of the phase(s) is usually the first step in the study of both bulk and thin-film materials. Qualitative analysis involves the identification of a phase or phases in a specimen by comparison with reference patterns from available databases, and relative estimation of proportions of different phases in multiphase specimens by comparing peak intensities attributed to the identified phases. For example, the Powder Diffraction File (Fawcett *et al.*, 2017) consists of a very large set of reference patterns (with 398 726 inorganic data sets and 526 126 organic data sets in 2017) provided by the International Centre for Diffraction Data (ICDD, formerly known as JCPDS).

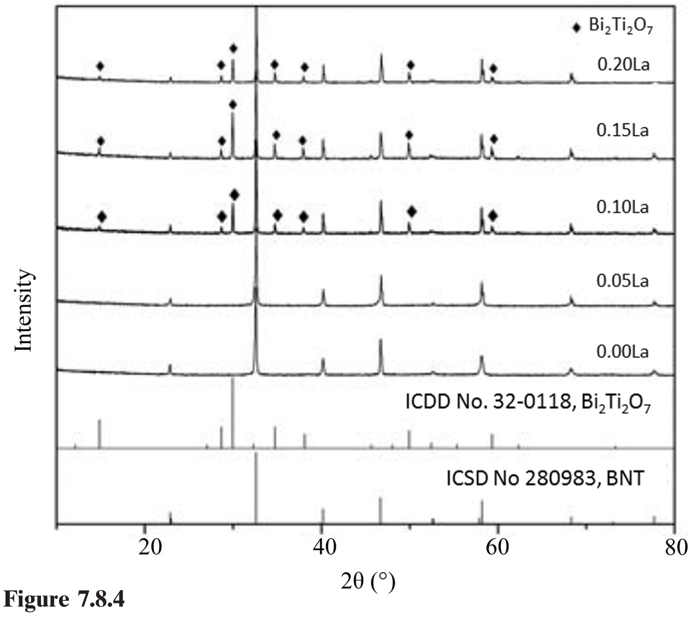

Figure 7.8.4

Often X-ray diffraction is used to characterize series of ceramic solid solutions to determine the homogeneity range of a single phase and to identify the presence of other impurity phases. As an example, $(Bi_{0.5}Na_{0.5})_{1-1.5x}La_xTiO_3$ (BNT) ceramics where x = 0, 0.05, 0.10, 0.15 and 0.20 were studied by Eaksuwanchai *et al.* (2012. These materials have potential applications as oxide thermoelectric compounds to directly convert heat to electricity or *vice versa*. Phase identification of these ceramics was carried out using the powder X-ray diffraction (XRD) technique (Fig. 7.8.4). The XRD patterns indicated that for La concentrations $x > 0.05$ all ceramic compositions contained a rhombohedral (or pseudo-cubic) BNT-based phase with formation of a secondary phase. Both the density and grain size of the ceramics decreased with increasing La content, and La-doped BNT ceramics became more electrically conducting despite the presence of a second phase in the matrix.

For phase identification of thin-film materials, the grazing-incidence X-ray and neutron diffraction (GID, GIXD, GIND) method allows the phase composition of a fabricated material to be probed as a function of depth from a surface (Tanner *et al.*, 2004). In brief, irradiation of a sample with an incident beam which is parallel and at a very low angle to the surface creates diffraction from the crystallites concentrated towards the surface. The depth of X-ray penetration is correlated with the incident angle; typical depth data can range from ~20 nm to approximately 10 µm. In other words, Bragg reflections only arise from the surface structure. An advantage of the grazing-incidence technique is that the electric field at the critical angle is amplified locally by a factor of four, making the signal stronger. A disadvantage is the limited in-plane spatial resolution. Typical applications for ceramic systems include studying changes in crystal structure influenced by deposition on top of a substrate, *e.g.* changes in the crystal form of TiO_2 (rutile *versus* anatase) towards the interface with metal substrates; and general characterization of ceramic layers deposited on a substrate with respect to phase identity, crystallite size and preferred orientation.

Grazing-incidence X-ray diffraction was used by Fritz *et al.* (2004) to show that a pentacene monolayer, grown on an amorphous ceramic α-quartz substrate [commonly used as a dielectric layer in organic thin-film transistors (OTFTs)], is crystalline. A preliminary energy-minimized model of the monolayer, based on the GIXD data, reveals that the pentacene molecules adopt a herringbone arrangement with their long axes tilted slightly from the substrate normal (Fig. 7.8.5). Although this arrangement resembles the general packing features of the (001) layer in single crystals of bulk pentacene, the monolayer lattice parameters and crystal structure differ from those of the bulk. Because carrier transport in pentacene OTFTs is likely to occur in the semiconductor layers near the dielectric interface, the discovery of a crystalline monolayer structure on amorphous SiO_2 has important implications for transport in OTFTs.

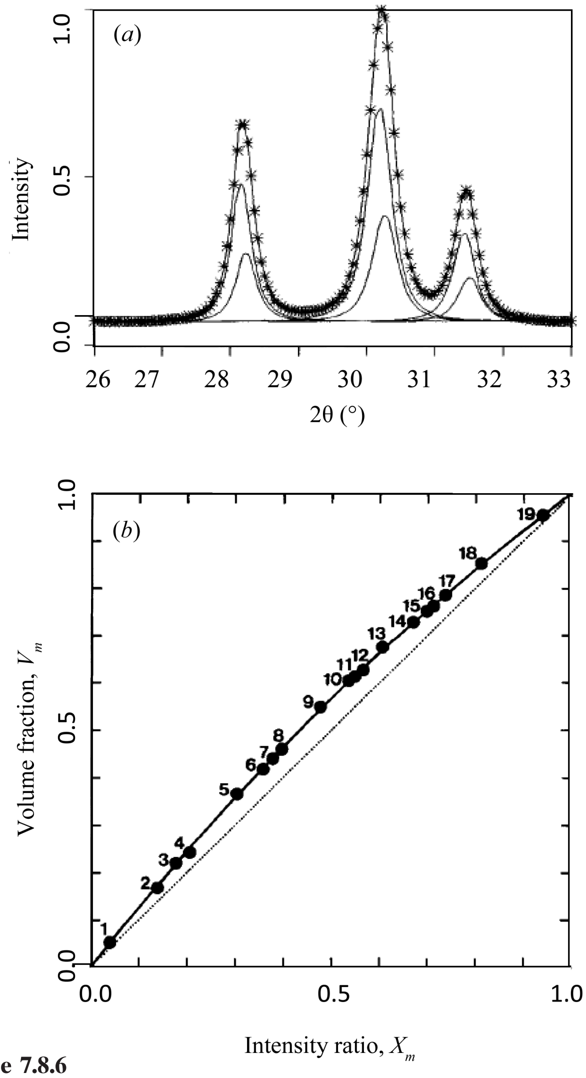

Figure 7.8.6

The $K\alpha$ and $K\alpha_1$ components of each reflection are also shown. (*b*) Volume fraction of monoclinic ZrO_z, V_m, *versus* intensity ratio, X_m, for the 19 samples. The intensity ratio (the polymorph method) underestimates the volume fraction of monoclinic ZrO_2. Reprinted with permission from Toraya *et al.* (1984). Copyright (1984) John Wiley and Sons.

7.8.3.1.2. *Quantitative analysis of phases*

Quantitative analysis using diffraction data usually refers to the determination of amounts of different phases in multiphase samples (see Chapter 3.9). All quantitative analysis requires precise and accurate determination of the peak positions and intensities of the diffraction pattern. Two general methods, the intensity-ratio method and the internal-standard method, have been used frequently for quantitative analysis. Rietveld refinement (Rietveld, 1969) also allows sophisticated quantitative treatments of phases present in a ceramic sample (Larson & Von Dreele, 2004; Rodríguez-Carvajal, 1993; Coelho, 2005). Since diffraction data are generally dependent on the systematics of the diffractometer and its data-collection system, application of quantitative methods that involve ratios of peak intensities requires careful calibration with well characterized standards.

As ZrO_2 is an important ceramic material, various quantitative analyses of this phase have been reported. In the classic paper by Toraya *et al.* (1984), a nonlinear calibration curve for volume fraction *versus* integrated intensity ratio was obtained for the monoclinic–tetragonal system by using X-ray powder pattern-fitting and pattern-decomposition techniques on 19 samples. They found that the pattern-decomposition technique can resolve the overlapping reflections into individual ones by a procedure similar to that of the pattern-fitting technique by disregarding the structure model (Parrish *et al.*, 1976). This technique was used to measure the integrated intensities of partially overlapping monoclinic ($\bar{1}11$) and (111) and tetragonal (101) reflections. Fig. 7.8.6(*a*) shows the pattern decomposition for one of the samples that exhibits the most striking partial overlap. The volume fractions of monoclinic ZrO_2 and intensity ratio X_m for the 19 samples are plotted in Fig. 7.8.6(*b*). Toraya *et al.* found that intensity-ratio method (Garvie & Nicholson, 1972) underestimates volume fraction of monoclinic ZrO_2. To suppress the error in X_m, the pattern-decomposition technique should be used. Schmid (1987) also obtained nonlinear calibration curves of weight fraction *versus* integrated intensity ratio for polymorphic mixtures of ZrO_2 by X-ray diffraction. Elshazly *et al.* (2011), by applying the modified Garvie and Nicholson method, were able to determine the monoclinic content of yttrium tetragonal zirconia biomaterials formed during a low-temperature aging process.

7.8.3.1.3. *Phase equilibria, crystal chemistry and crystallography*

Phase diagrams are critical research tools for many scientific disciplines including materials science, ceramics, geology, physics, metallurgy, chemical engineering and chemistry. Phase diagrams contain important information for the development of new materials, control of structure and composition of critical phases, and improvement of properties of technologically important materials. These diagrams often can be thought as 'road maps' for processing, as they provide the theoretical basis for the synthesis of materials. Applications of phase diagrams range from preparation of high-quality single crystals and single-phase materials to controlled precipitation of second phases and formation of melts.

As phase diagrams provide critical information for the scientific community, there are various world centres that are responsible for the compilation of these diagrams. For over 60 years, the American Ceramic Society (ACerS), in collaboration with NIST, has evaluated and published the *Phase Diagrams for Ceramists* series of compilations. Since the cooperative program between NIST and ACerS was formalized in 1982, computerization of data was established as a major goal to modernize the book products. More than 27 600 entries have been published in the CD-ROM product and in 21 book volumes. The continuous growth rate is about 500 new commentaries (with 1000 phase diagrams) per year. These products have provided high-quality phase-equilibrium data of ceramic phases to the technical community (ACerS–NIST Phase Equilibria Diagrams, 2018; https://www.nist.gov/srd/nist-standard-reference-database-31).

The preparation of an equilibrium phase diagram is a long process that requires a committed effort using a combination of methods (Carter, 1978; Roth & Vanderah, 2004). For example, to construct subsolidus phase diagrams, a number of compositions are prepared in the region of interest, followed by equilibration and determination of the phase assemblages present. Homogeneity regions and tie-lines connecting phases in equilibrium are determined by studying the evolution of these compositions as a function of time, temperature and pressure. The experimental methods for determining phase diagrams are generally divided into two types: static and dynamic. In the static methods, the temperature of the sample is held constant until equilibrium is attained. Quenching studies in combination with powder X-ray diffraction and petrographic microscopy for phase identification are essential for obtaining subsolidus phase diagrams. Dynamic techniques, including differential thermal analysis (DTA) and thermogravimetric analysis (TGA), are needed to obtain an indication of phase transitions, reactions and associated loss of volatiles such as oxygen. Electron-beam-based methods such as transmission electron microscopy (TEM) and scanning electron microscopy (SEM) are used to further define the microstructures of the experimental products, particularly of the crystalline phases. Quantitative micro-beam analytical techniques, including energy-dispersive X-ray analysis (EDS) or wavelength-dispersive methods (WDS), are used for the determination of the compositions of both the crystalline phases and the quenched liquid.

7.8.3.1.4. *Phase evolution*

As nanoceramics find important applications in many fields of modern electronics including medical appliances, there is an increasing need to understand the process of phase evolution of these materials. Quite often, combined use of several techniques such as *in situ* powder diffraction, the pair distribution function (PDF) approach (Billinge, 2004; see also Chapter 5.7), TEM and modelling has proved to be useful for understanding phase formation during crystallization as well as the local structure.

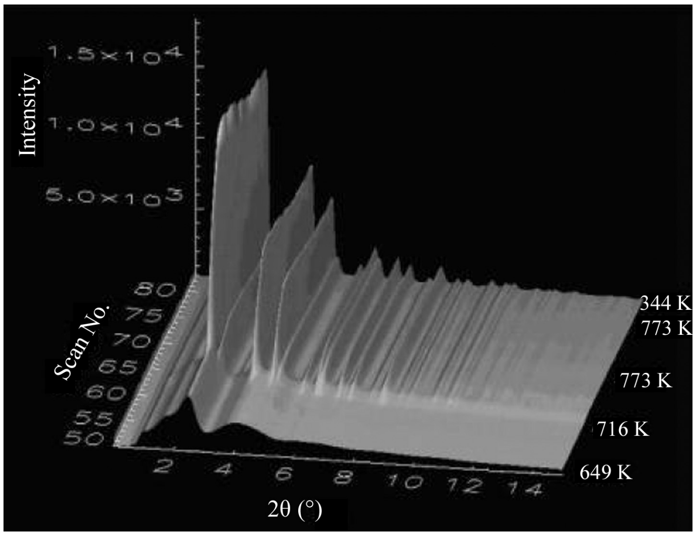

Figure 7.8.7
In situ XRD patterns demonstrating the phase transition from amorphous to cubic ZrO_2 in a reducing atmosphere. Reprinted with permission from Zhang *et al.* (2007). Copyright (2007) American Chemical Society.

High-temperature X-ray diffraction (HTXRD) is very useful for *in situ* studies to characterize phase evolution as a function of temperature. Pair distribution function (PDF) analysis and combined reverse Monte Carlo (RMC) simulation can also be used to study the details of local structure during the phase-evolution process. As an example, the amorphous-to-cubic crystallization of nano-ZrO_2 in a reducing environment was studied by *in situ* synchrotron X-ray diffraction (Zhang *et al.*, 2007). Rietveld analysis was performed to study the changes in crystallite size and lattice parameters as the cubic phase emerged. Fig. 7.8.7 illustrates *in situ* XRD patterns demonstrating the phase evolution from amorphous to cubic ZrO_2 in a reducing atmosphere. The PDF was obtained from the Fourier transformation of the normalized XRD patterns. A reverse Monte Carlo simulation was used to provide details of the local structure during the crystallization process as well as to calculate partial PDFs for Zr–Zr and Zr–O during the crystallization. It was found that the number of next-nearest neighbours of Zr remains at 12, whereas the number of O atoms as nearest neighbours of Zr increases from 6.7 to 7.3 as the material evolves from an amorphous into a cubic structure, suggesting the persistence of a high concentration of oxygen vacancies. These simulated atomic structures show that the local structure of the amorphous phase bears a resemblance to the short-range arrangement of cubic ZrO_2, consistent with the results of X-ray absorption near edge spectroscopy (XANES) at the Zr $L_{\rm II}$ and $L_{\rm III}$ edges. It was concluded that the amorphous-to-crystalline phase evolution is affected by the environment. Under an oxidizing environment, the amorphous phase crystallizes directly to tetragonal and subsequently to monoclinic zirconia.

In another example, phase evolution during firing of ceramic bodies from three different marine sediments was investigated as a function of temperature (Romero *et al.*, 2009). The mineralogical evolution was examined by XRD and revealed that quartz, which is a main crystalline phase in the original marine sediments, remains as a main phase in the sintered bodies in all three sediments. A glassy phase and new crystalline phases appear as result of different chemical reactions during firing. For

example, Fig. 7.8.8(*a*) shows the XRD pattern of one of the sediments (astilleros) heat-treated in the range 1273–1423 K. Fig. 7.8.8(*b*) plots the change in the amorphous phase by considering the background intensity at the position of the (100) quartz reflection. Although the amount of quartz undergoes a slight increase at the beginning of sintering process, it tends to decrease with heating temperature. The glassy phase shows an inverse behaviour. Increasing the sintering temperature gives rise to a partial dissolution of quartz grains and therefore the amount of glassy phase increases. Scanning electron microscopy (SEM) showed a homogeneous microstructure composed of pores, crystals and a ceramic matrix. Energy X-ray dispersive spectroscopy (EDS) analyses permitted differentiation of the crystalline phases previously identified by XRD from minor phases, which were not detected in the X-ray diffraction.

7.8.3.1.5. *Phase transformation*

The physical properties of technological ceramic materials are strongly dependent on their composition as well as their microstructure. The most efficient way of obtaining the desirable microstructure is *via* accurate control of phase transformations in these solids. The structure resulting from a solid-state phase transformation depends intimately on the crystallographic relationship between the Bravais lattices of the initial and product phases, on the elastic moduli of the separate phases, on the kinetics (or rate) of the transformation and on the processing environment.

Broadly speaking, a phase transition is the transformation of a thermodynamic system from one phase or state of matter to another. In solid-state processes, there are several different types of phase transformation. Multicomponent systems may not only involve a reorientation of the crystal lattice under consideration, but also some degree of atomic diffusion from the parent phase to the final sintered product. One example would be the transition from iron(II) oxide to iron(III) oxide. The formation of the product phase would be limited by the rate of diffusion of O atoms through the surface of the parent FeO layer. Alternatively, there are many phase transformations that are not limited by diffusion, but result simply from some form of thermomechanical instability of the crystal lattice, and may require a diffusionless structural transition from one crystallographic lattice to another. These displacive or diffusionless transformations are called martensitic, and typically involve a thermally induced shear of the unit cell constituting the Bravais lattice in the parent phase. Other types of solid-state transformation include: spinodal decomposition, in which a single phase is cooled and separates into two different compositions of that same phase; the transition between the ferromagnetic and paramagnetic phases of magnetic materials at the Curie point; and order–disorder transitions.

An example in Fig. 7.8.9 shows that a biphasic mixture of $CeNbO_{4+\delta}$ produced using solid-state synthesis techniques has undergone transformation in air to the tetragonal modification at 915 K (Skinner & Kang, 2003). This transformation process involves an initial oxidation stage where the overall stoichiometry increases to $\delta \simeq 0.38$. On cooling of the sample a single $\delta \simeq 0.25$ phase is produced. On repeating the thermal treatment with the now single-phase material, it was evident that no transformation to the $\delta \simeq 0.38$ phase occurred, but the tetragonal modification was observed at the same temperature as previously. Furthermore, the high-temperature tetragonal modification was found to be stable above 1023 K with an oxygen excess concentration corresponding to a stoichiometry of $CeNbO_{4.21}$.

7.8.3.2. *Structure and microstructure*

7.8.3.2.1. *Crystal structure*

Powder diffraction using X-ray, neutron, synchrotron and electron diffraction techniques (or any combination of these) has played a central role in structural analysis. Important advances in

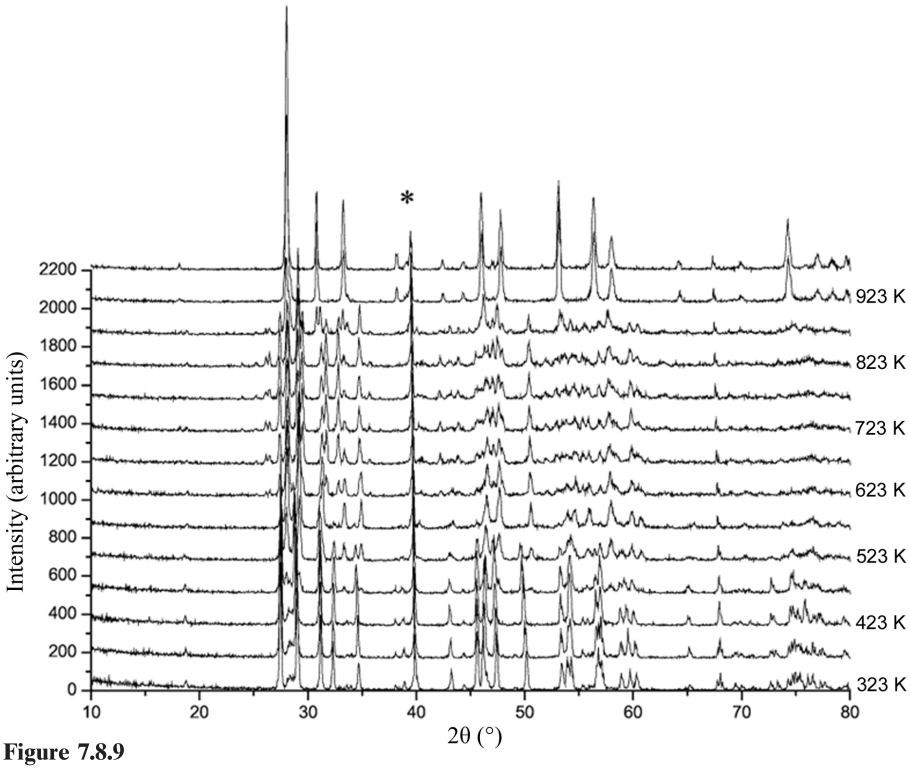

Figure 7.8.9

structural studies of ceramic materials of all classes were due to the renaissance of powder-diffraction techniques in the past several decades. By far the majority of these structures have been analysed using the Rietveld method (Rietveld, 1969; Larson & Von Dreele, 2004; Rodríguez-Carvajal, 1993; Coelho, 2005), a development which has greatly enhanced the power of powder-diffraction experiments. As the Rietveld technique is a refinement technique that requires a known structural model, the technique has its limitations. In recent years, tremendous development has been reported in terms of both the techniques and applications of *ab initio* powder structural solution (David *et al.*, 2002; see also Part 4 of this volume). The advancement of this technique is particularly important for ceramic materials in view of the fact that it is often difficult to grow single crystals of these. Even with the advances of synchrotron single-crystal diffraction, wherein one needs only crystals of micron size, the ability to solve the structure with an *ab initio* technique is extremely valuable. Other techniques that are useful for studying the local structure of a material include pair distribution function analysis (Billinge, 2004; Chapter 5.7) and extended X-ray absorption fine structure (EXAFS) (Koningsberger & Prins, 1988), which are important for local structure analysis for ceramic/nanoceramic materials.

Examples of successful ceramic structure studies using Rietveld refinement are abundant. In particular, using neutron diffraction, one can determine magnetic structures, where the magnetic spins also play a role in determining the overall structure (Vanderah *et al.*, 1997; Rodriguez *et al.*, 2005; Tachibana *et al.*, 2003). Vanderah *et al.* (1997) used low-temperature neutron powder diffraction to study the magnetic structure of a $Ba_4Fe_2Ti_{10}O_{27}$ phase which is a candidate microwave material for cellular communication applications. At room temperature this phase has an open-framework type structure with a monoclinic unit cell and space group *I*2/*m*. However, the magnetic structure exhibits $P12'$ symmetry and is illustrated in Fig. 7.8.10(*a*). The magnetic arrangement features two sets of collinear spins, (Fe1 + Fe4) and (*M*2 + *M*3) (where *M* denotes mixed Fe/Ti sites), with antiferromagnetic ordering within each set. The two sets correspond to the two types of polyhedra occupied by Fe^{3+}, as illustrated in Fig. 7.8.10(*b*). Segregation of the spins into two sets could be caused by the different types of exchange pathway permitted by the two polyhedral linkage patterns. The octahedral sites (*M*2 + *M*3) share edges, hence a pathway exists for direct Fe–Fe exchange in addition to 90° superexchange *via* shared oxygen sites. In contrast, the tetrahedral sites are vertex-linked, thus magnetic interactions occur *via* superexchange only.

Further examples of magnetic structure studies were illustrated by Rodriguez *et al.* (2005), using neutron powder diffraction. By combining Rietveld and pair distribution function analysis of the total neutron scattering data, they obtained the local and long-range structure of $La_{0.5}Ca_{0.5}MnO_3$ at room temperature and at 20 K. Tachibana *et al.* (2003) successfully used combined X-ray and neutron diffraction to study the influence of substitution ratio and oxygen partial pressure on the magnetic structure of an iron-substituted *Z*-type hexagonal barium ferrite, $Ba_3Co_{2-x}Fe_{24+x}O_{41}$ (x = 0–0.6).

7.8.3.2.2. *Crystallite size*

There are several diffraction approaches to studying the crystallite size of ceramic materials, ranging from traditional to new. Crystallite size is the size of a single crystal domain inside the particles or grains. A grain can be composed of several crystals. The size of the diffracting crystallites is often important in describing the reactivity of a ceramic material, because surface area increases with decreasing particle size (see Chapter 5.1). The Scherrer equation (Scherrer, 1918; Patterson, 1939) gives a first approximation of the value for this quantity:

$$L = K\lambda/(\beta\cos\theta),$$

where L is the mean crystallographic dimension in the same units as the wavelength λ, K is a constant near unity, β is the width of a peak at half height in radians and corrected for instrumental factors, and θ is the location of the peak. This equation was developed in 1918 to calculate nanocrystallite size (L) by X-ray diffraction of radiation of wavelength λ (nm) from measuring the full width at half maximum of peaks (β) in radians located at any 2θ in the pattern. The shape factor, K, can be 0.62–2.08 and is usually taken as about 0.89. However, the Scherrer equation may underestimate crystallite size, because it does not account for effects of atomic substitutions. A variety of factors can contribute to the width of a diffraction peak; besides crystallite size, the most important of these are inhomogeneous strain and instrumental effects. If all of these other contributions to the peak width were zero, then the peak width would be determined solely by the crystallite size and the Scherrer formula would apply. If the other contributions to the width are non-zero, then the crystallite size can be larger than that predicted by the Scherrer formula, with the 'extra' peak width coming from the other factors.

Monshi *et al.* (2012) provided a new approach to the use of the Scherrer equation, using a least-squares technique to minimize the sources of errors. The Scherrer equation shows systematically increased values of nanocrystallite size as d values decrease and 2θ values increase. Modified Scherrer equation plots of $\ln\beta$ against $\ln(1/\cos\theta)$ give the intercept of a least-squares regression line, $\ln = K\lambda/L$, from which a single value of L is obtained through all of the available peaks. They demonstrated this technique for a natural hydroxyapatite (HA) from bovine bone fired at 673, 873, 973, 1173 and 1373 K (Fig. 7.8.11) from which nanocrystallite sizes of 22.8, 35.5, 37.3 and 38.1 nm, respectively, were obtained; 1173 K was selected for biomaterials purposes. These results show that the modified Scherrer equation method is promising in nanomaterials applications and can distinguish between 37.3 and 38.1 nm by using the data from all of the available peaks.

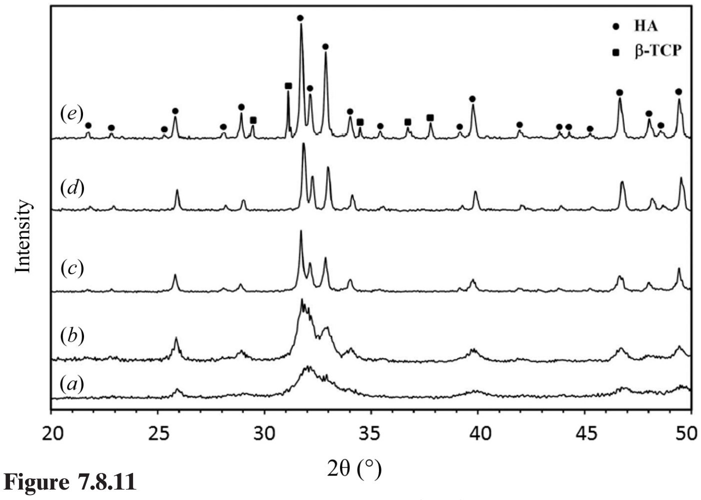

Figure 7.8.11

When the sample also contains residual strain, one can use the Williamson–Hall approach (Williamson & Hall, 1953) and the Warren–Averbach approach (Warren & Averbach, 1950). In recent years, the Rietveld refinement technique has been well developed to compute crystallite size and residual strain using known structural models (see Chapter 5.2). For example, Balzar & Popa (2002) proposed a model to yield complete texture-weighted strain and stress tensors as a function of crystallite orientation, and improved the size-broadened profile by a combination of Gaussian and Lorentzian functions.

7.8.3.2.3. *Imperfection (defects) in ceramics*

Defects in ceramics occur quite frequently and are partly responsible for various physical properties of ceramic materials, particularly their mechanical and electronic properties (Cai & Nix, 2016). The brittle fracture of ceramics limits their applications. The flaws that are produced during ceramic processing cannot be closely controlled; this leads to a large variability in the fracture strength of ceramic materials. The contaminants form flaws which eventually lead to crack formation. Crack propagation (perpendicular to the applied stress) is usually transgranular along cleavage planes. Common defects can be categorized in several types: 0D (zero-dimensional) point defects (atomic point defects, stoichiometric defects, non-stoichiometric defects and extrinsic defects), 1D defects (dislocations) and 2D defects (planar defects).

The following example illustrates the influence of sintering temperature and pressure on lattice defect structure (dislocation

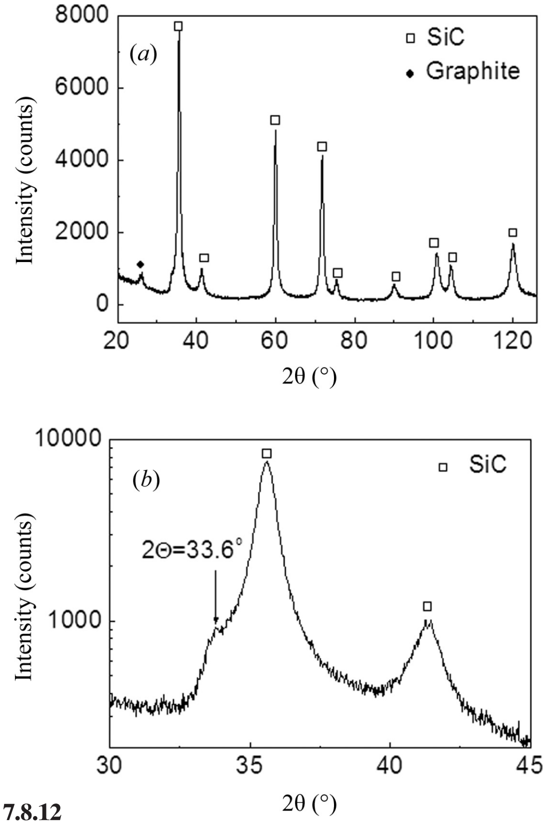

Figure 7.8.12
(*a*) X-ray powder pattern for the sample sintered at 2 GPa and 2073 K. (*b*) The X-ray diffraction pattern calculated for 10% twins for the 2θ range 30–45° (Gubicza *et al.*, 2007).

and planar fault densities and twins) and crystallite size in a series of sintered nanocrystalline SiC specimens by X-ray line profile analysis using the convolutional multiple whole profile (CMWP) fitting procedure (Gubicza *et al.*, 2007). The lattice defect structure and the crystallite size are determined as a function of pressure between 2 and 5.5 GPa for sintering temperatures in the range from 1673 to 2073 K. The X-ray powder pattern for the sample sintered at 2 GPa and 2073 K for the 2θ range between 30 and 45° is shown in Fig. 7.8.12(*a*). The X-ray diffraction pattern calculated for 10% twins is plotted in Fig. 7.8.12(*b*) for the 2θ range between 30 and 45°. The small peak at 33.6° is unambiguously related to planar faults. In the Williamson–Hall plots the FWHM values of the 111/222 and 200/400 reflection pairs are order-independent, indicating that line broadening is mainly caused by small crystallite size and/or planar faults. In summary, the sintering process results in an increase of the crystallite size. In the case of relatively small crystallite size values, *i.e.* less than about 20 nm, planar faults are the main lattice defects, while for crystallite sizes larger than 70 nm dislocations are more abundant.

7.8.3.2.4. *Residual stress measurements of ceramic components*

Residual stress is defined as 'the stress resident inside a component or structure after all applied forces have been removed'. Compressive residual stress acts by pushing the material together, while tensile residual stress pulls the material apart. Mechanical and thermal processes applied to a component during service may also alter its residual stress state. In general, compressive residual stress in the surface of a component is beneficial because it tends to increase fatigue strength and fatigue life, slow crack propagation, and increase resistance to environmentally assisted cracking. On the other hand, tensile residual stress in the surface of the component is generally undesirable as it decreases fatigue strength and fatigue life, increases crack propagation and lowers resistance to environmentally assisted cracking (Jones & Berard, 1993). Therefore, knowledge of the residual stress state is important to determine the actual loads experienced by a ceramic component.

Residual stresses can be characterized by the scale at which they exist within a material. Stresses that occur over long distances within a material are referred to as macro-stresses. Stresses that exist only locally (either between grains or inside a grain) are called micro-stresses. The total residual stress at a given location inside a material is the sum of all three of the following types of stresses:

(i) Type-I stresses: macro-stresses occurring over distances that involve many grains within a material.

(ii) Type-II stresses: micro-stresses caused by differences in the microstructure of a material and that occur over distances comparable to the size of the grain in the material. They can occur in single-phase materials because of the anisotropic behaviour of individual grains, or can occur in multiphase material as a result of the presence of different phases.

(iii) Type-III stresses: exist inside a grain as a result of crystal imperfections within the grain.

A number of different methods are available to measure residual stress; however, only a few are quantitative. X-ray diffraction is a nondestructive method which allows the measurement of residual stress in isolated spots spaced at distances as small as 100 μm apart. Neutron diffraction is an alternative nondestructive method which also allows measurement of residual stress in isolated spots. The choice between these two techniques depends on the design of the mechanical part to be tested.

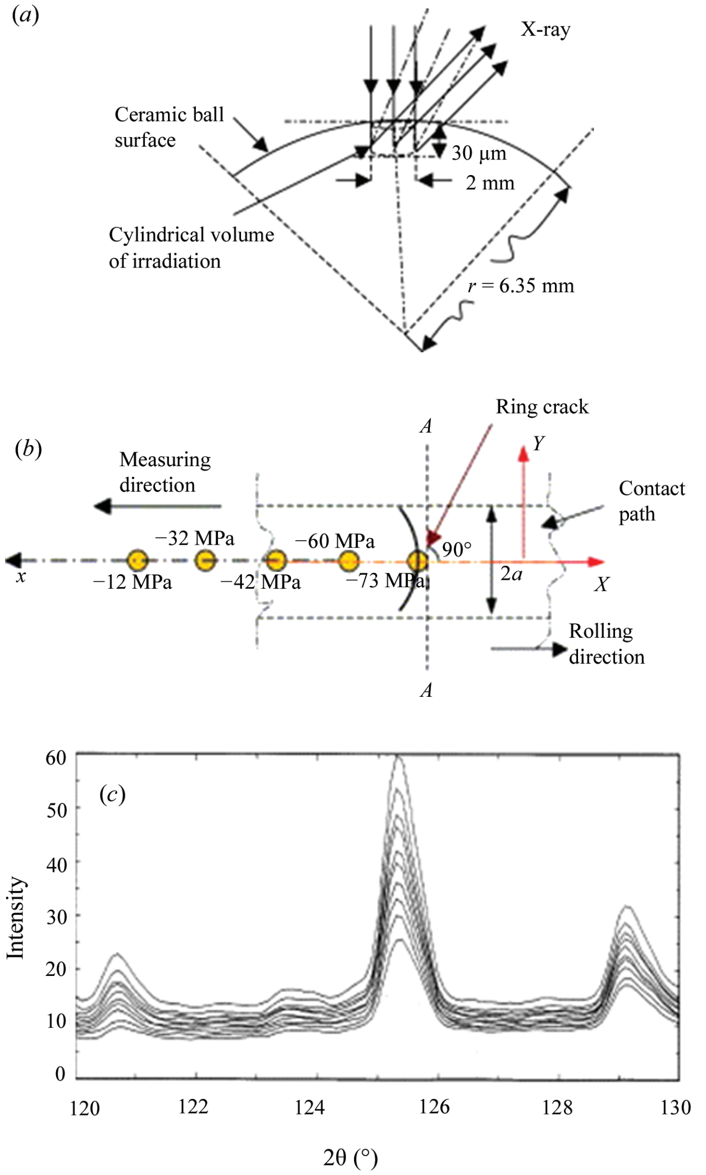

Figure 7.8.13

(*b*) Measurement points and direction on the ball surface. (*c*) Ten measurements performed and averaged using data smoothing. Reproduced with permission from Khan *et al.* (2005). Copyright (2005) Elsevier.

The following example demonstrates X-ray residual stress measurement results of rolling contact fatigue on Si_3N_4 ceramic bearing elements with refrigerant lubrication using residual stress measurement testing methodology (Khan *et al.*, 2005). Analysing the relationship of residual stress with rolling contact fatigue is an important study which provides guidelines on the design, process and manufacturing of these elements. The rolling bearing elements were pre-cracked by inducing a ring crack and indents on the ball surface. The standard diffractometer method is called the two-exposure method (Cullity, 1978). Fig. 7.8.13(*a*) gives a schematic of the Si_3N_4 ceramic ball cylindrical volume taken for the residual stress measurements which were performed within the circle. Fig. 7.8.13(*b*) gives the measurement points and direction on the ball surface. Ten measurements were performed and averaged using data smoothing (Fig. 7.8.13*c*). The characteristic of this study was the small volume of irradiation. The X-ray beam penetrated sub-surface within the material to a depth

of 30 µm. Stress measurement was taken from a cylindrical volume of 0.0942 mm^3. Khan *et al.* found that low compressive residual stress values indicate a higher number of stress cycles attained, *i.e.*, the compressive residual stress values decreases with increase in stress cycles. A compressive residual stress value of −73 MPa near the ring crack and a comparatively lower value of −12 MPa on the contact indicate sub-surface crack initiation and propagation (Fig. 7.8.13*b*). The average fatigue spall ranged from 100 to 148 µm in depth. Within the spall area residual stress measurements suggest that compressive residual stress is relieved much faster in the region of sub-surface damage.

7.8.3.2.5. *Texture/preferred orientation*

In polycrystalline ceramic materials, the orientation of the crystallites is not usually distributed randomly, such as in an ideal powder specimen. In most cases, a preferred orientation of the crystallites with respect to the sample reference frame is present. Preferred orientation or texture of ceramics (Bunge, 1995) arises when there is a stronger tendency for the crystallites in a powder or a texture to be oriented more in one way, or one set of ways, than all others. An easily visualized case of preferred orientation in ceramics is that which results when a material with a strong cleavage or growth habit is packed into a specimen. Texture is responsible for many macroscopic properties of ceramic materials. For example, in the ceramic high-T_c superconductor materials, texturing of grains is important to improve the critical current density, J_c, by diminishing weak links. When the oxide grains are aligned, the current can go in one direction by utilizing adjacent layers of grains. Knowledge of the texture is an important factor in understanding the mechanical, physical or chemical behaviour of the material investigated.

Texture analysis is a diffraction technique in which the orientation distribution of the crystallites constituting a sample is determined (Bunge, 1995; Chapter 5.3). In X-ray diffraction analysis, the texture is determined from a set of pole figures. These pole figures are measured by recording the intensity distribution of a single reflection by tilting and rotating the sample over the orientation sphere. In this way the orientation distribution of a single reflection, and thus for a single lattice plane, is determined. When a set of pole figures for independent crystal orientations has been measured, the orientation distribution function (ODF) of the crystallites can be calculated.

An example of the study of the correlation of the texture of ceramic materials with enhanced properties can be illustrated by the state-of-the-art ceramic thermoelectric material $Ca_3Co_4O_9$ (Guilmeau *et al.*, 2005). $Ca_3Co_4O_9$ (or $[Ca_2CoO_3]_{0.62}[CoO_2]$) is a misfit layered oxide that has two monoclinic subsystems with identical cell parameters *a*, *c* and *β*, but different *b* (Masset *et al.*, 2000). The first subsystem consists of triple rock-salt layers of Ca_2CoO_3 in the *ab* plane while the second subsystem consists of a single CoO_2 layer, which has the CdI_2-type structure. This phase exhibits strong anisotropic thermoelectric properties in the *ab* plane. It is thought that the increased scattering of phonons at the interface of misfit layers leads to the lowering of the lattice thermal conductivity.

The texture analysis of highly grain-aligned ceramics of $Ca_3Co_4O_9$ prepared by the reactive-templated grain growth (RTGG) process that involved uniaxial pressing was examined by an quantitative texture-analysis technique using X-ray diffraction (fibre texture strength and crystallite size) as a function of pressing time. An X-ray diffraction pattern shows *c*-axis alignment of the tape-cast sample where platelets were aligned along the casting plane (only 00*l* peaks were observed); the (003) crystallographic planes for various χ angles (Fig. 7.8.14*a*) were used to study the orientation distribution of the *c* axes from the normal to the casting plane. After integration and renormalization of these peaks, the distribution of the orientation densities (inverse pole figure) (Fig. 7.8.14*b*) shows a strong centred pole as a sign of preferred orientation. The calculated {003} inversed pole figure of a sample with a pressing duration time of 2 h that was derived from the ODF for the direction normal to the casting plane is shown in Fig. 7.8.14(*c*). The texture increase is correlated with an enhancement of thermoelectric properties, and with larger electrical conductivity and power factor, as a function of pressing duration time.

7.8.3.2.6. *Thickness and roughness of ceramic films*

Structural characterization and determination of the thickness of ceramic thin films can be achieved with grazing-incidence X-ray diffraction (GIXD). Using the previous example of pentacene on an α-quartz substrate, GIXD yields a monolayer film thickness, 16.0 ± 0.6 Å (Fritz *et al.*, 2004).

X-ray reflectivity measurement is a nondestructive technique that provides microscopic information about the roughness, density profile and thickness of the layers that compose the thin film, and it offers advantages over ellipsometry in that precise information about the properties of buried layers can be obtained. The interface structure, thermal stability and densification of several ceramic ZrO_2 thin films [deposited from aqueous solution on Si(100) substrates] in the temperature range from room temperature to 1023 K in vacuum were measured by Ritley *et al.* (2000) using the high-temperature *in situ* X-ray reflectivity technique with a six-circle diffractometer. The reflectivity data for the ZrO_2 sample, as well as for a bare surface and self-assembled monolayers (SAMs) of an organic surface-covered Si substrate are shown in Fig. 7.8.15. Their detailed analysis showed that the growth rate of film is a nonlinear function of time in solution. The as-deposited films exhibit about 3 nm roughness and a density below that of bulk ZrO_2. Measurements in vacuum reveal decreasing film thickness, increasing film density and decreasing roughness upon annealing up to 1023 K. The densification saturates at the highest measured temperatures, presumably following evaporation of residual contaminants from the aqueous synthesis procedure. Above 473 K the SAM/ZrO_2 interface began to deteriorate, possibly due to interdiffusion. The ZrO_2 film structure obtained at the highest annealing temperatures persisted upon cooling to room temperature, and there was no visible evidence of stress-induced microstructural changes, such as peeling or cracking.

7.8.3.3. *Processing and performance*

7.8.3.3.1. *Sintering/densification/grain growth*

Sintering, which is based on atomic diffusion, is traditionally used for manufacturing ceramic objects from powders. Diffusion occurs in any material above absolute zero, but it occurs much faster at higher temperatures. In most ceramic sintering processes, the powdered material is subjected to high pressure and heated to a temperature below the melting point. The atoms in the powder particles diffuse across the boundaries of the particles, fusing the particles together and creating one solid piece. The different paths that the atoms take to get from one place to another are known as the sintering mechanisms. The six common mechanisms are: (1) lattice diffusion from a grain boundary, (2) grain boundary diffusion, (3) plastic deformation, (4) surface diffusion, (5) vapour transport and (6) lattice diffusion from the surface. Mechanisms (1) to (3) are densification mechanisms as atoms are moved from the bulk to the surface of pores, thereby eliminating porosity and increasing the density of the sample (Barsoum, 2003).

Sintering in practice is the control of both densification and grain growth. Sintering is effective when the process reduces the porosity and enhances properties such as strength, electrical conductivity, translucency and thermal conductivity. Densification is the act of reducing porosity in a sample thereby making it denser. Grain growth is the process of grain-boundary (GB) motion to increase the average grain size [a grain boundary is the transition area or interface between adjacent crystallites (or grains) of the same chemical and lattice composition]. Owing to the shifted positioning of the atoms in the GB, they have a higher energy state than the atoms in the crystal lattice of the grains. The driving force for densification is the change in free energy from the decrease in surface area and lowering of the surface free energy. Many properties benefit from both a high relative density

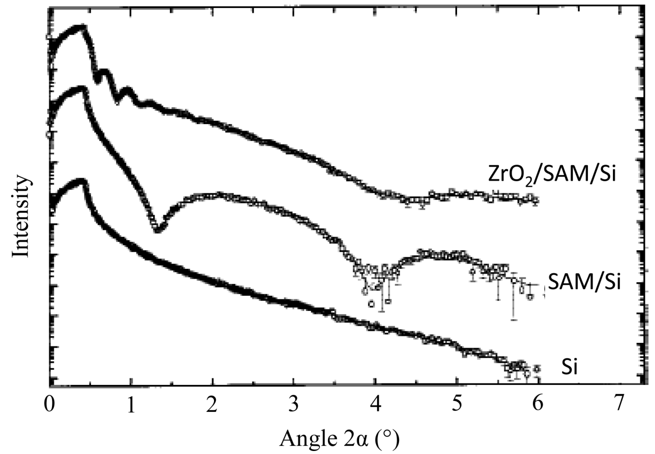

Figure 7.8.15

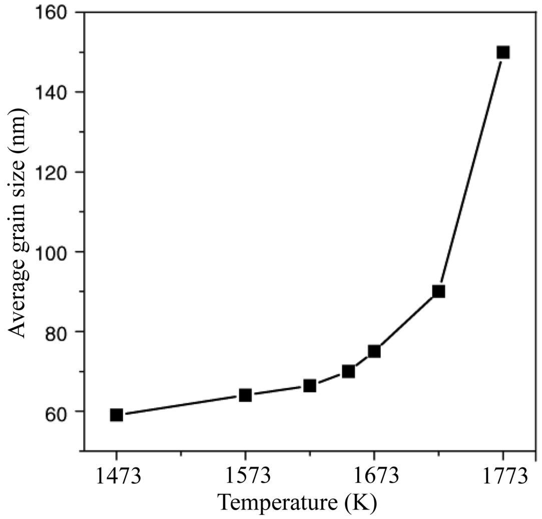

Figure 7.8.16
The average grain size of Al_2O_3 nanoceramics from an α-Al_2O_3 nanopowder with a mean particle size of 10 nm pressed at 1120 MPa as a function of the sintering temperature (with a fixed sintering time of 1 h). Reproduced with permission from Li & Ye (2006). Copyright (2006) John Wiley and Sons.

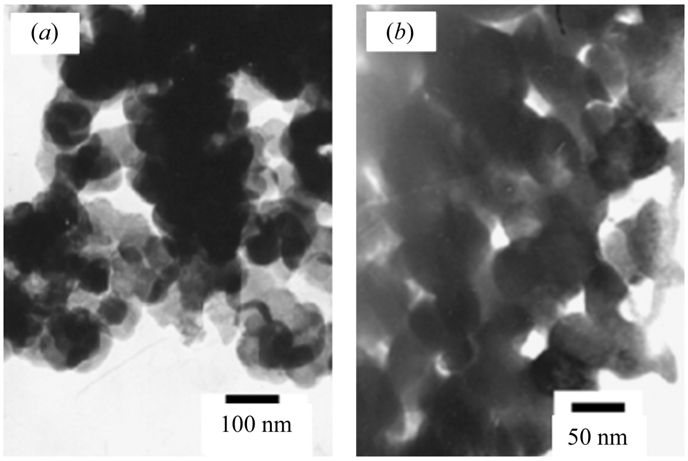

Figure 7.8.17
Transmission electron microscopy micrographs of Al_2O_3 nanoceramics from an α-Al_2O_3 nanopowder with a mean particle size of 10 nm pressed at 1120 MPa and sintered according to two different programmes: (*a*) sintering at 1723 K for 1 h and then at 1623 K for 34 h; (*b*) sintering at 1653 K for 1 h and then at 1603 K for 50 h. Reproduced with permission from Li & Ye (2006). Copyright (2006) John Wiley and Sons.

and a small grain size. Therefore, being able to control these properties during processing is of high technical importance.

In one study (Li & Ye, 2006), α-Al_2O_3 nanopowders with mean particle sizes of 10, 15, 48, and 80 nm (synthesized by the doped α-Al_2O_3 seed polyacrylamide gel method) were used to sinter bulk Al_2O_3 nanoceramics. It was found that the relative density of the Al_2O_3 nanoceramics increases with increasing compaction pressure on the green (unsintered) compacts and with decreasing mean particle size of the starting α-Al_2O_3 nanopowders. The Al_2O_3 nanoceramics with an average grain size of 70 nm (estimated from the corresponding X-ray peak broadening) and a relative density of 95% were obtained by a two-step sintering method. Fig. 7.8.16 shows that there was no fast grain growth observed in the second step of sintering below 1723 K. Transmission electron microscopy (TEM) micrographs showing the density and average grain size of the Al_2O_3 nanoceramics sintered by a two-step sintering method are shown in Fig. 7.8.17. It is seen that the average grain size of 70 nm in the Al_2O_3 nanoceramics sintered at 1653 K for 1 h and then sintered at 1603 K for 50 h (Fig. 7.8.17*b*) is smaller than that of the 90-nm Al_2O_3 nanoceramics sintered at 1723 K for 1 h and then sintered at 1623 K for 34 h (Fig. 7.8.17*a*). The densification and the suppression of the grain growth are achieved by exploiting the difference in kinetics between grain-boundary diffusion and grain-boundary migration (by the slower grain-boundary diffusion without promoting grain growth in second-step sintering).

7.8.3.3.2. *Reaction mechanisms/sequence*

In order to understand both the physical and chemical properties of ceramic materials, detailed knowledge of the reaction mechanisms that lead to phase formation of a desired ceramic phase is essential. Combined techniques such as powder diffraction, scanning electron microscopy (SEM), differential thermogravimetric analysis (DTA), nuclear magnetic resonance (NMR) and Raman spectroscopy have proved to be beneficial. Among these techniques, the *in situ* diffraction technique is indispensable. For ultra-fast ceramic reactions, in recent years, we can also use ultra-high-speed diffraction or synchrotron diffraction to study the reaction mechanisms. The following two examples illustrate the power of these state-of-the-art techniques.

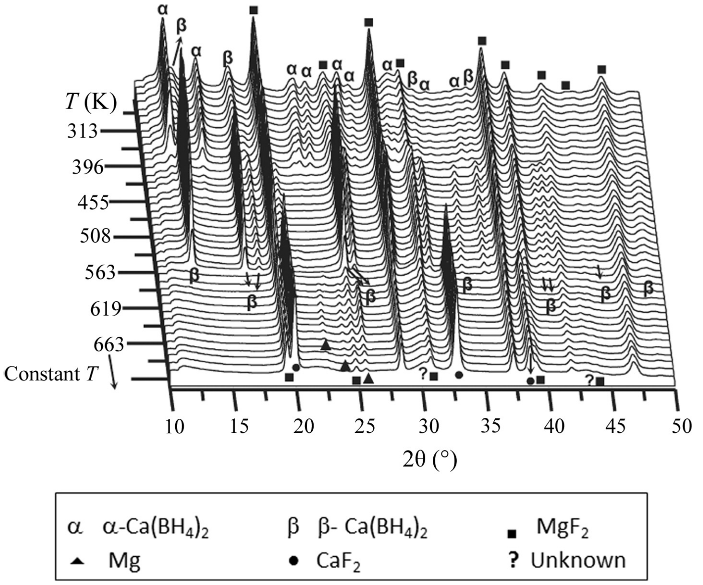

Figure 7.8.18
Synchrotron-radiation powder X-ray diffraction (SR-PXD) spectra of milled $Ca(BH_4)_2$–MgF_2 under a vacuum with the temperature programme of (i) heating from 298 to 663 K and (ii) dwelling at 663 K for 1 h. Reprinted with permission from Gosalawit-Utke *et al.* (2011). Copyright (2011) American Chemical Society.

The reaction mechanisms and kinetic properties of the $Ca(BH_4)_2$–MgF_2 reversible hydrogen storage process were studied by Gosalawit-Utke *et al.* (2011). The dehydrogenation and rehydrogenation reaction mechanisms were investigated by *in situ* time-resolved synchrotron-radiation powder X-ray diffraction (SR-PXD) and Raman spectroscopy. During dehydrogenation, the milled $Ca(BH_4)_2$–MgF_2 was heated to 663 K under a vacuum and held at 663 K for 1 h. Fig. 7.8.18 shows the SR-PXD patterns of milled $Ca(BH_4)_2$–MgF_2 with the temperature programmes of (1) heating from 298 to 663 K and (2) dwelling at 663 K for 1 h. At about 431 and 586 K, the polymorphic transformation from α- to β-$Ca(BH_4)_2$ and the melting of β-$Ca(BH_4)_2$ took place, respectively. At about 553 K the intensity of MgF_2 peaks decreased, indicating that the fluorine atoms in CaF_2 were obtained from MgF_2. Raman spectroscopy revealed the presence of CaB_6 together with amorphous α-boron. The dehydrogenation products were thus deduced to be CaF_2, CaB_6, Mg and α-B. The $Ca(BH_4)_2$–MgF_2 composite indicates kinetic destabilization and the reproducibility of hydrogen-storage capacities during cycling.

In situ neutron diffraction at 0.9 s time resolution was used by Riley *et al.* (2002) to determine the reaction mechanism during the self-propagating high-temperature synthesis (SHS) of Ti_3SiC_2 from furnace-ignited stoichiometric 3Ti + SiC + C mixtures. Ti_3SiC_2 is an important ceramic because of its unique properties of high melting point, good high-temperature strength, resistance to corrosion and oxidation, and high electrical and thermal conductivity, which are both ceramic and metallic in nature. The diffraction patterns indicate that the SHS proceeded in five stages: (i) preheating of the reactants, (ii) the $\alpha \rightarrow \beta$ phase transformation in Ti, (iii) pre-ignition reactions, (iv) the formation of a single solid intermediate phase in <0.9 s, and (v) the rapid nucleation and growth of the product phase Ti_3SiC_2. No amorphous contribution to the diffraction patterns from a liquid phase was detected and, therefore, it is unlikely that a liquid phase plays a major role in this SHS reaction. The intermediate phase is believed to be a solid solution of Si in TiC such that the overall stoichiometry is approximately 3Ti:1Si:2C. Lattice parameters and known thermal-expansion data were used to estimate the ignition temperature as 1196 ± 10 K (supported by the $\alpha \rightarrow \beta$ phase transformation in Ti) and the combustion temperature as 2593 ± 50 K.

Examples of studies of other reaction sequences/mechanisms include using combined X-ray diffraction and solid-state ^{29}Si and ^{27}Al magic-angle spinning NMR spectroscopies to monitor the initial formation of amorphous SiO_2, and to detect the formation of a noncrystalline mullite-like aluminosilicate which becomes crystalline at high temperatures (Mackenzie, 1997).

7.8.3.3.3. *Kinetics and reaction rate*

Diffraction techniques (particularly high-temperature setups) can be used to characterize ceramic reactions, including bulk materials and the interaction of ceramic films with buffer materials or substrates. Combining the diffraction technique with electron energy-loss spectroscopy/energy-dispersive spectroscopy (EELS/EDS) measurements and TEM, one can derive the kinetic rate laws and activation energies for the reactions. Examples include reaction kinetics of various classes of ceramic materials, such as formation of nanostructured silicon carbide (Wallis *et al.*, 2008), kinetic investigation of yttrium tetragonal zirconia biomaterials (Elshazly *et al.*, 2011), high temperature X-ray diffraction (HTXRD) study of reactions rates in the formation of ceramic Aurivillius phases (Peterson *et al.*, 2003), formation of one-dimensional hierarchical titania for enhanced reaction kinetics of photoanode materials of dye-sensitized solar cells (Qu *et al.*, 2010), optimized formation of magnesium ferrite (Paik *et al.*, 2005), formation of $CuInSe_2$ thin-film solar cells and reaction kinetics of the superconductor $Ba_2YCu_3O_{6+x}$ with CeO_2 (Cook *et al.*, 2007; Wong-Ng *et al.*, 2005).

The study of the reaction of the superconductor oxide $Ba_2YCu_3O_{6+x}$ with a buffer layer material, CeO_2, is illustrated (Cook *et al.*, 2007; Wong-Ng *et al.*, 2005). A $Ba_2YCu_3O_{6+x}$ film was deposited on CeO_2 pellets using a laser deposition technique. Sequential X-ray diffraction patterns of a $Ba_2YCu_3O_{6+x}$ pellet heat-treated at 1103 K for increasing cumulative time (min) are shown in Fig. 7.8.19. In most ceramic reactions, there is an interface between reacting phases. The overall process involves transport of material to the interface, reaction at the interface, and sometimes transport of reaction products away from the interface. For a reaction in which a compound is formed as the planar reaction layer, the rate of product formation is controlled by diffusion through the product layer. The reaction kinetics are expected to obey the parabolic rate rule $x = Kt^{1/2}$ (where x is the thickness of the reaction layer, t is the time and K is a constant related to the rate constant). The plots of intensity *versus* $t^{1/2}$ for the experiments at 1083 K are shown in Fig. 7.8.20. For the reaction products $Ba(Ce,Y)O_3$ (reflection 213) and BaY_2CuO_5 (reflection 131), the shape of the plots are rather similar. There is a straight-line portion for a relatively short reaction time period, and then the rate of change of intensity decreases. While the intensities of reflections from the products increase, the intensity of the reflection from the reactant, namely $Ba_2YCu_3O_{6+x}$, decreases. The intensity *versus* $t^{1/2}$ plots for the experiments at 1103 K are similar to those of 1083 K, except that at higher temperature the reaction progresses faster. For example, the reaction to form $Ba(Ce,Y)O_3$ was nearly complete at $t^{1/2} \sim 13.5$ min$^{1/2}$, while at 1083 K the corresponding time parameter was at 23 min$^{1/2}$. At 1063 K, the reaction was still occurring at $t^{1/2} = 60$ min $^{1/2}$. A bright-field image of a cross section of a sample provided information on the thickness of a monophasic

$Ba(Ce,Y)O_3$ reaction product layer. The fact that a monophasic product layer of $Ba(Ce,Y)O_3$ was formed adjacent to the CeO_2 suggests that the reaction occurred primarily by diffusion of Ba into the CeO_2. This process left behind products of BaY_2CuO_5 and CuO. One can deduce the K values at 1063 and at 1103 K. The activation energy ($E_{\rm act}$) for the reaction can be deduced to be 2.67×10^5 J mol^{-1} using the Arrhenius equation, $K1/K2 = [A\exp(-E_{\rm act}/RT_1)/A\exp(-E_{\rm act}/RT_2)]$, where A is a pre-exponential factor and R is the universal gas constant.

7.8.3.3.4. *Transformation toughening*

The traditional interest in the mechanical behaviour of ceramics is often related to their use as structural materials. Considerable effort has been expended to produce structural ceramics with enhanced toughness. In recent years, the applications have expanded to dental inlays, crowns and bridges. Toughening mechanisms that remain effective at high temperatures are still not totally understood. The toughening mechanisms include transformation toughening, toughening by a metallic particulate phase and fibre reinforcement. The most promising toughening mechanism for ceramic materials involves a phase transformation. Transformation toughening is based on the idea that a phase transformation can be stress-induced in a material in such a way that it decreases the driving force that is acting to propagate that cracks that are present, or that can form under stress in the material.

Although other materials such as alumina can be transformation-toughened, zirconia (ZrO_2) is the prototype material for this process. ZrO_2 is one of the most studied ceramic materials. It adopts a monoclinic crystal structure at room temperature and undergoes first-order phase transitions to tetragonal and cubic forms at higher temperatures. The volume expansion caused by the cubic-to-tetragonal-to-monoclinic transformation induces large stresses, and these stresses cause ZrO_2 to crack upon cooling from high temperatures. When the zirconia is blended with some other oxides, the tetragonal and/or cubic phases are stabilized, and the resulting material has superior thermal, mechanical and electrical properties. Effective dopants include magnesium oxide (MgO), yttrium oxide (Y_2O_3, yttria), calcium oxide (CaO) and cerium(III) oxide (Ce_2O_3) (Green *et al.*, 1989; Callon *et al.*, 2000). In some cases, the tetragonal phase can be metastable. If sufficient quantities of the metastable tetragonal phase are present, then an applied stress, magnified by the stress concentration at a crack tip, can cause the tetragonal phase to convert to monoclinic, with the associated volume expansion. This phase transformation can then put the crack into compression, retarding its growth, and enhancing the fracture toughness. This mechanism is known as transformation toughening. In Fig. 7.8.21, a crack and its surrounding transformation zone are shown schematically. The zone can be described as a large transformation inclusion that is constrained by the surrounding material. The transformation within the zone tries to make the zone larger, but this is opposed by the surrounding untransformed material (Callon *et al.*, 2000).

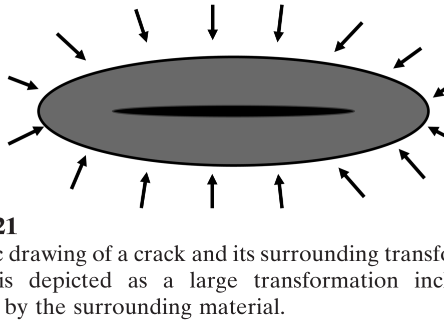

Figure 7.8.21
A schematic drawing of a crack and its surrounding transformation zone. The zone is depicted as a large transformation inclusion that is constrained by the surrounding material.

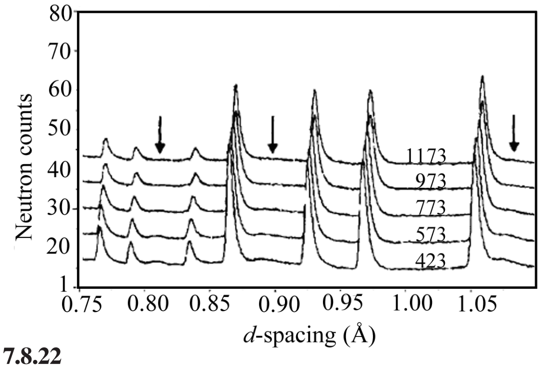

Figure 7.8.22
Comparison of neutron-diffraction profiles at 423, 573, 773, 973 and 1173 K for 8 mol% yttria-stabilized zirconia. The locations of low-temperature diffuse peaks are marked with arrows. Reproduced with permission from Gibson & Irvine (1996). Copyright (1996) Royal Society of Chemistry.

A comprehensive study of 8 mol% yttria-stabilized zirconia between 423 and 1273 K was carried out by Gibson & Irvine (1996) using high-temperature neutron powder diffraction and AC impedance spectroscopy. It was been demonstrated that the conductivity anomaly, which occurs at *ca* 923 K, is structural in origin. A sharp decrease in the activation energy for conduction of *ca* 0.2 eV was observed at *ca* 923 K. Additional broad, diffuse-scattering peaks were observed below 873 K in the neutron diffraction patterns (Fig. 7.8.22); above 923 K, the diffuse-scattering peaks disappeared. The low-temperature behaviour can be explained in terms of ordering of oxygen vacancy–(dopant) cation clusters to form microdomains, which are evidenced by the presence of diffuse-scattering peaks. At high temperature, the association of vacancies with defects breaks down, or randomizes, allowing vacancies to move more freely, as indicated by the decrease in activation energy for conduction. A discontinuity in the thermal-expansion coefficient (from neutron diffraction data) confirms the second-order nature of the transition.

7.8.3.3.5. *Degradation/corrosion of ceramics*

Corrosion is the local or extensive reaction of a material or component with a surrounding medium. Corrosion is a diffusion-controlled process. It occurs on exposed surfaces, and it degrades the useful properties of materials and structures including strength, appearance and permeability or impermeabilitiy to liquids and gases. Corrosion accelerates subcritical crack propagation under mechanical strain. Almost all environments are corrosive to some extent. For practical applications it is a matter of kinetics. The cost of corrosion to ceramics is enormous. McCauley (1995) discussed the fundamentals (corrosion by liquids, by gas, by solids; effects of porosity, surface energy, acid/base, thermodynamic/kinetics). Methods of corrosion analysis and test procedures are illustrated here with several examples.

Technical ceramics are relatively more stable than common metallic materials towards corrosion (except for the refractory carbides, silicides, nitrides and borides). When corrosion does occur in oxides, it is almost always a simple dissolution of the material or chemical reaction. A common example of corrosion protection in ceramics is the lime added to soda-lime glass to reduce its solubility in water. Normal glass forms sub-microscopic

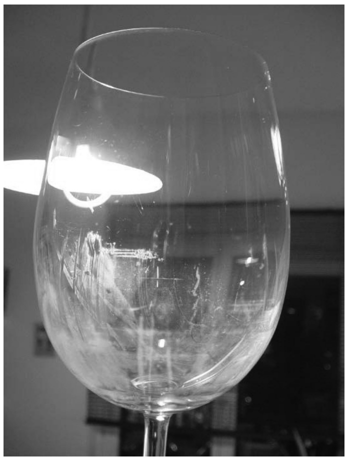

Figure 7.8.23
A wine glass plagued by 'glass disease'.

flaws when exposed to moisture. The corrosion of silicate glasses in aqueous solutions, which is known as 'glass disease', is governed by two mechanisms: diffusion-controlled leaching (ion exchange) and hydrolytic dissolution of the glass network. Fig. 7.8.23 shows a wine glass plagued by 'glass disease'.

Another example shows attack of a mullite refractory by glass. A mullite refractory was removed from the regenerator division wall of a soda-lime-silicate container glass furnace (McCauley, 1995). X-ray diffraction results showed that the mullite has completely converted to predominantly corundum and nepheline. The optical micrograph in Fig. 7.8.24 (with combined analysis from SEM/EDS) showed that the crystalline nepheline was embedded in a matrix of vitreous potassium titanium silicate. The potassium diffused into the refractory from glass batch impurities and the titanium was present in the original refractory in minor amounts.

Zirconia has also found wide application in dentistry because of its high mechanical strength and superior aesthetic properties (Kawai *et al.*, 2011). However, zirconia degradation caused by phase transformations occurring in a hydrothermal environment is of concern. In the study by Kawai *et al.* (2011), the phase transformation and microstructure of tetragonal zirconia polycrystals partially stabilized with yttrium oxide (Y-TZP) and alumina-toughened zirconia (ATZ) sintered at different temperatures were investigated. Using grazing-angle X-ray diffraction analysis, ATZ showed less phase transformation to the monoclinic phase than Y-TZP during hydrothermal treatment and this transformation appeared to occur to a depth of a few micrometres below the surface. Fig. 7.8.25 shows XRD patterns of zirconia by both the 2*θ*–*θ* method and the grazing-angle method (at 1 and 2°). At a higher sintering temperature the monoclinic phase content of ATZ was found to be less than that of Y-TZP (Fig. 7.8.26*a*,*b*). Examination by transmission electron microscopy (TEM) and studying of electron backscatter diffraction patterns indicated that the grain growth in ATZ was slightly suppressed compared with that in Y-TZP at higher sintering

X-ray patterns recorded on a powdered sample of an LZSA glass ceramic with a composition of 16.9Li_2O–5.0ZrO_2–65.1SiO_2–8.6Al_2O_3 in the temperature range 923–1223 K (Montedo *et al.*, 2012). Peak labels: Z = ZrO_2, ZS = $ZrSiO_4$, S = spodumene.

temperatures. Therefore, alumina addition appears to suppress hydrothermal degradation to a larger extent than the addition of yttria.

7.8.3.3.6. *Glass ceramics (crystallization processes)*

Diffraction techniques, particularly *in situ* high-temperature diffraction techniques, are very valuable for studying glass-ceramic crystallization processes.

LZSA glass ceramics (Li_2O–ZrO_2–SiO_2–Al_2O_3) have been studied because of their beneficial thermal, mechanical and thermal properties (Montedo *et al.*, 2012). The crystallization sequence of an LZSA glass ceramic with a composition of 16.9Li_2O–5.0ZrO_2–65.1SiO_2–8.6Al_2O_3 was investigated using combined techniques of HTXRD, differential thermal analysis (DTA) and scanning electronic microscopy (SEM). X-ray patterns recorded on a powdered sample in the temperature range 923–1223 K are shown in Fig. 7.8.27. It is seen that at room temperature the material is essentially vitreous except for traces of zirconia (monoclinic ZrO_2). Crystallization of β-spodumene solid solution was found to commence at approximately 943 K. A pronounced acceleration was observed at temperatures above 998 K. Above 1023 K $ZrSiO_4$ crystallized as the major phase with the maximum amount reached at 1173 K. A wide variety of other glass-ceramic systems have been studied, *e.g.* the Li_2O–Al_2O_3–$n$$SiO_2$ (LAS) system, the MgO–Al_2O_3–$n$$SiO_2$ (MAS) system, the ZnO–Al_2O_3–$n$$SiO_2$ (ZAS) system and the MgO–SiO_2–Al_2O_3–K_2O–B_2O_3–F system (Ghasemzadeh *et al.*, 2011).

7.8.3.3.7. *Microstructure evolution*

The nondestructive (both neutron and synchrotron) small-angle-scattering technique has been used for many years to study the microstructure of intermetallic materials. In the past three decades, there has been an increase in the use of this technique. Details of the technique have been reported extensively elsewhere and will not be described here (Allen, 2005; see also Chapter 5.8). In brief, neutrons are an excellent nondestructive probe of microstructure because thermal neutron energies are very low and neutrons are not absorbed by most materials. Since the neutrons primarily interact with the nuclei of the atoms, the neutron beam is highly penetrating without disturbing the sample, so one can examine the bulk of the material, whereas X-ray and other techniques are more sensitive to surface phenomena.

Small-angle neutron scattering (SANS) techniques are used to study microstructural phenomena in the range 1 to 100 nm in size. Since these techniques cover a wide range of sizes, they are particularly useful in studies of ceramic processing and distributed damage in ceramics. Ceramics often have several microstructural components, such as residual voids from the sintering process, inclusions or impurities from starting materials, second phases, and microcracks or cavities from temperature and/or pressure treatments, as well as dislocations present in the material. All these effects result in small-angle neutron scattering signal. Beam-broadening theory and the SANS technique (Hardman-Rhyne *et al.*, 1984) allow us to study the microstructure development of ceramic materials in a nondestructive way. An example of the sintering of spinels ($MgAl_2O_4$) as a function of temperature is shown in Fig. 7.8.28. Although the spinel powders have been heated at 1603 K for 12 h, very little sintering has taken place, but sintering effects are apparent after only 3 h at 1773 K. The material is not fully sintered in that ε_b (the full width at half maximum of the direct beam, the blank) is much smaller than ε for the spinel at 1773 K.

7.8.3.3.8. *Bulk modulus/compressibility*

All ceramic materials can stretch, compress, bend, flex, shear, twist or deviate from their original unstressed shapes and dimensions when subjected to external forces or internal thermal stresses. The tendency of ceramic materials to deform is an important consideration in the design of any ceramic component whose operation depends on its ability to sustain loads or to maintain dimensions within specified tolerances: one needs to have information on the toughness of a ceramic material.

To estimate the toughness (K_{IC}) of a material quantitatively, it is necessary to know the value of Young's modulus (Y) for the solid. For ceramic materials, the latter parameter can be deter-

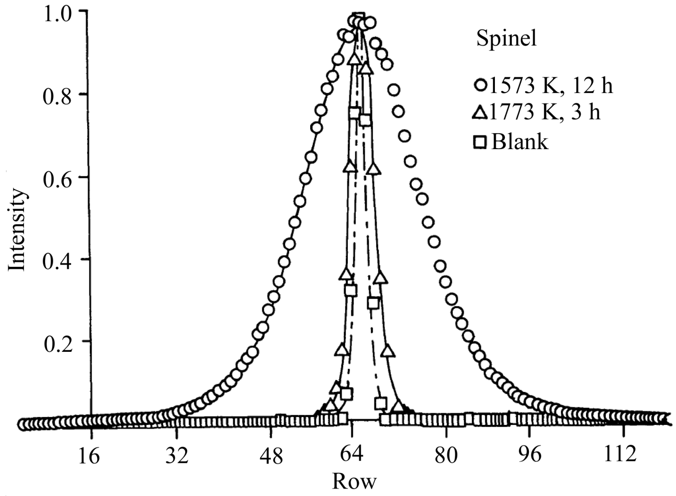

Figure 7.8.28
SANS spectra for a spinel ($MgAl_2O_4$) at λ = 0.9 nm. The circles represent the SANS spectra of the spinel with 12 h of heat treatment at 1573 K. After 3 h at 1773 K (triangles) the spinel is partially sintered but slight neutron-beam broadening can be seen compared with that of the direct beam (squares) (Hardman-Rhyne *et al.*, 1984).

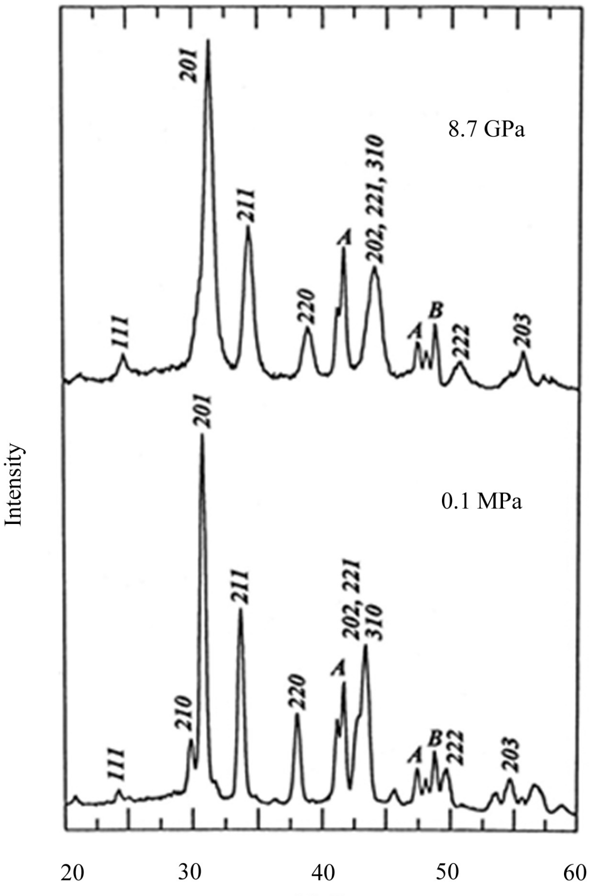

Figure 7.8.29

mined from measurements of the bulk modulus, or its inverse, the compressibility, which can be determined by powder-diffraction techniques. K_{IC} is related to the Young's modulus, Y, by $K_{IC} = (Y/H)^{1/2}\ (L/C_0^{1.5})$. From indentation experiments, one can obtain the value of L (load), C_0 (indentation length) and H, the hardness. Y is in turn obtained from $Y = 3k(1 - 2\sigma)$, where k is the isothermal bulk modulus and σ is Poisson's ratio.

Powder-diffraction techniques also allow the lattice parameters to be evaluated at each state of compression. The isothermal equation of state can in turn be determined. If the compressibility dependence shows linear dependence, a first-order isothermal equation (the Bridgman equation) is usually used to compute the bulk modulus, $V = V_0 - (V_0/k)(P - P_0)$, where V is the volume, P is the pressure and k is the bulk modulus. The isothermal bulk modulus is then estimated using the thermodynamic relation $k = -V(\mathrm{d}P/\mathrm{d}V)_T$. It is possible to measure the bulk modulus of a ceramic material using a high-pressure measurement technique, which utilizes a diamond anvil high pressure cell (DAC) with energy-dispersive powder diffraction, as first developed at the National Bureau of Standards. The detailed history of its invention in the 1950s, its modification and its many applications have been described in a review article by Piermarini (2001) and the references cited therein. The DAC has been used with both conventional X-ray, synchrotron X-ray and neutron diffraction techniques. The compressibility and bulk modulus of many ceramic materials with different applications have been obtained using the DAC. Examples include zinc-blende solids (Cohen, 1985), tobermorite (a structural analogue of calcium silicate hydrates) (Oh *et al.*, 2012), β-boron (Nelmes *et al.*, 1993), $BaY_2Cu_3O_{6+x}$ (Block *et al.*, 1987), $Pb(N_3)_2$, $Ba(N_3)_2$, KN_3, TlN_3 and NaN_3 (Weir *et al.*, 1970).

Another example of this application is the study of $BaNd_2CuO_5$ (Wong-Ng *et al.*, 1995). A total of 221 data points were measured from ambient pressure up to about 8.7 GPa. The tetragonal unit-cell parameters for each pressure studied were obtained by indexing and performing least-squares refinements on the powder patterns (Fig. 7.8.29 shows two of the patterns, measured at 0.1 and 8.7 GPa). A linear least-squares fit of the volume compression of $BaNd_2CuO_5$ was obtained within a 99% confidence envelope along with uncertainties associated with pressure and volume. The equations of states for the tetragonal cell parameters, a, c and V are $a = -0.0139P + 6.700$, $c = -0.0125P + 5.807$, $V = -1.615P + 260.62$. A first-order Bridgman equation was used to compute the bulk modulus, k= 161.4 GPa. The Young's modulus, Y, was calculated to be 193.6 GPa, assuming a Poisson's ratio σ of 0.3.

7.8.4. Summary

Perhaps contrary to general public's perception of ceramics as primarily encompassing artwork, tableware, porcelain enamels, tiles and sanitary ware, ceramics cover a broad range of materials and applications. In this chapter, we have attempted to categorize these materials in terms of both their functions and applications, from traditional ceramics to modern advanced ceramics.

Powder diffraction has repeatedly been shown to provide the most critical and versatile tools for the characterization of many different aspects of ceramic materials. As many ceramic materials (regardless of their applications) exhibit similar features during processing and manufacturing (sintering and grain growth, texture, residual strain, microstructure evolution *etc.*), the applications of diffraction techniques have been demonstrated with selected representative applications.

In many cases, the combined use of powder diffraction (laboratory X-ray, synchrotron X-ray, neutron diffraction, electron diffraction) with other tools or specialized techniques (such as DTA,TGA, SEM, EDS, WDS, XANES, EXAFS, SANS, solid-state NMR, Raman spectroscopy, AC impedance spectroscopy, ellipsometry and modelling approaches) is either absolutely necessary or greatly beneficial for the characterization of the specific ceramic material at hand.

Although this chapter does not represent a complete range of the applications of powder diffraction to ceramics materials, it illustrates the typical types of studies and approaches that are pertinent to these diverse materials. It introduces some readers to the functions of ceramic materials in today's world, where many new applications continually being found. For more in-depth understanding of the theories behind various powder-diffraction applications, as well as more detailed descriptions of various applications of diffraction techniques to ceramic materials, other chapters of this volume should be consulted.

The author is grateful to the Fine Ceramics Office, Ministry of International Trade and Industry, Tokyo, for providing the chart on functions and applications of fine/advanced ceramics. 7.9. Applications in glass-ceramics

S. T. Misture

7.9.1. Introduction

Glass-ceramics find application in a broad range of technologies largely because they are easily processed to form crystalline solids with a wide range of grain sizes, grain morphologies and properties. Glass-ceramics are perhaps more correctly described as composites of crystalline and glassy phases with grain sizes ranging from nanometres to micrometres. The unique aspect of glass-ceramic processing is net-shape forming. During manufacture, the starting glass is melted and can be formed into a net or near-net shape using well known glass-forming techniques that produce full-density glasses. After shaping, the glass may then be subjected to an appropriate time–temperature excursion to induce partial or full crystallization, also called 'ceramization'. It should be noted that the crystallization of the glass begins from a full-density solid, which is a condition that cannot be achieved using traditional ceramics powder manufacturing techniques, and hence glass-ceramic microstructures are often considered superior to polycrystalline ceramic bodies that typically contain some fraction of closed porosity.

Our ability to control the phase assemblage and microstructure of glass-ceramics leads to a broad range of technological applications, with the ubiquitous example being transparent nano-grained cookware. Other examples include high-temperature ceramic-to-metal sealants used in commercial lighting, electrochemical devices, electronics packaging *etc*. In healthcare, glass-ceramics find application in dental restorations and for a range of biomedical devices, bone cements and the like.

7.9.1.1. *Devitrification*

Generically, 'glass-ceramics' include any composite material with a varying crystal-to-glass ratio, with the crystalline content approaching 100% in many cases. Glass-ceramic devices or components are typically fabricated in one of two ways: forming to net shape using glass-forming methods, or processed as powder to near-net shape. After forming, nucleation and crystallization is induced by an appropriate heat treatment to create a glassy matrix with crystalline grains. This process is called devitrification, although the term 'ceramization' is also often used. It is important to note that the glassy component may be small enough to ignore for most discussions of the microstructure–property relations in glass-ceramic bodies.

When using glass-forming methods, the advantage of the glass-ceramic method is the ability to form fully dense net-shape components without the need for traditional ceramic consolidation and sintering processes. However, it is often necessary to process glass-ceramics in powder or frit form to accommodate surface nucleation, as will be described in detail later. Crystallizing glass is a two-step process, understood as nucleation and growth, where both processes have strong temperature dependences. Nucleation is the clustering of atoms of some critical size so that the nucleus may either grow to become a crystal or redissolve. Nucleation rate shows a peak with temperature; initially it increases with temperature above some critical nucleation temperature, then after reaching a peak value the rate decreases at higher temperature as more and more nuclei redissolve. Crystal growth rates also show a peak with temperature, but of course growth of a crystal requires a stable nucleus and hence the onset of crystallization occurs at or above the onset of nucleation. In general, the nucleation and growth curves are separated in temperature. Nucleation generally occurs at lower temperatures and growth at higher temperatures, but both occur simultaneously over some temperature range. Often the nucleation and growth curves overlap extensively, but for some systems the nucleation and growth temperatures are well separated. Hence it is sometimes possible to study nucleation and crystallization as separate events.

Nucleation occurs *via* one of three mechanisms, two of which are understood as 'bulk' nucleation and the third of which is surface nucleation. The defining characteristic of 'bulk'-nucleated glasses is nucleation within the glass instead of at surfaces of the glass or at interfaces of the glass. The first of the bulk mechanisms is homogeneous nucleation induced by phase separation in the amorphous state. Many glasses undergo phase separation to form two or more amorphous phases either during cooling or during reheating as part of the devitrification cycle. Phase separation in the amorphous phase may be detected in the diffraction pattern as a change in the amorphous hump(s). Partitioning of the chemical elements in the glass into two or more new glass phases may result in one or more of the new glasses having a lower stability than the starting bulk glass. Unstable glassy phases then nucleate tiny seed crystals, which subsequently grow to produce crystallites.

Secondly, the use of bulk nucleating agents (for example some metals, ZrO_2 or TiO_2) is common to induce nucleation in homogeneous glasses that do not undergo phase separation.

Finally, surface nucleation is an alternative mechanism where low-energy surface sites nucleate crystals. The use of frit processing is common when taking advantage of surface nucleation, where the glass frit particle size can be easily controlled to define the surface-to-bulk ratio and hence the density of nuclei, and the number and size of crystals.

The maximum crystallite size is determined by the volume density of nuclei, because the crystal nuclei grow during an appropriate heat treatment. As crystals grow in the glass, they eventually impinge on one another or consume all of the necessary chemical components from the glass. Nano-grained, transparent glass-ceramics can be routinely processed by simply increasing the volume density of nuclei.

Of course not all materials may be fabricated using the glass-ceramic process, either because the composition cannot feasibly be melted to form a glass or because crystallization of the glass does not produce the desired crystalline phase. The complexities of the nucleation and crystallization process can often, however, be used to great advantage. Common devitrification processes include the following.

(i) The simple case of crystallization of the glass to form crystals of the same stoichiometry as the glass (referred to as stoichiometric crystallization).

(ii) Crystallization of phases that are of different chemistry to the parent glass, therefore changing the composition of the glassy matrix as crystallization proceeds.

Copyright © 2019 International Union of Crystallography

(iii) Crystallization of metastable phases that transform with time into stable crystalline phases, thus facilitating synthesis of the metastable or stable phase, depending upon the heat-treatment time–temperature profile.
(iv) Crystallization of more than one phase, either concurrently or sequentially.
(v) Crystallization of different phases at the surface and in the bulk.

Processes (ii)–(v) yield a glassy matrix with different chemistry and therefore different properties to the starting glass, showing how the formation of glass-ceramics is an elegant way to tune the properties of monolithic solids. By simply controlling the nucleation and time–temperature profiles for a glass of given composition, one may produce solids with vastly varied properties. Perhaps even more elegant is the use the glass-ceramic method to produce unusual microstructures, because the crystals may grow as spherulites, as plates or in other interesting morphologies (Pinckney & Beall, 2008). Therefore, the glass-ceramic method is a unique tool in the design and processing of materials.

7.9.1.2. *Applications of powder diffraction*

The use of powder diffraction in the study of glass-ceramics is well established, although only relatively few laboratories use *in situ* high-temperature neutron powder diffraction (NPD) or X-ray powder diffraction (XRD), which will be the focus of this chapter. Glass crystallization is often studied using thermal analysis, either differential scanning calorimetry (DSC) for glasses with lower crystallization temperatures, T_x, or differential thermal analysis (DTA) for those with higher T_x. Well established methods, described later, can be used to extract the reaction kinetics and therefore the energetics of the crystallization process. Thermal analysis methods do not, however, provide any information about the crystallite size, microstrain, crystallite orientation or phase content. In contrast, diffraction methods provide direct access to all of these characteristics from a single measurement.

7.9.2. Methods

Powder diffraction may be used to track the crystalline phase fraction using any of the several quantitative analysis procedures outlined in Chapter 3.9, including absolute quantification of the amorphous and crystalline content. Crystallite growth can be determined using the diffraction peak broadening (see Chapter 5.1) as the crystals grow from ~5 to 1000 nm, where ~1000 nm is the limit of the technique. The third important characteristic is crystallite orientation relative to surfaces for monolithic glasses. Many glasses display nucleation and oriented growth starting at the surface, and hence quantification of the crystallite orientation may be important. Pole-figure measurements and quantitative orientation distribution functions (see Chapter 5.3) may be used to understand the crystallite orientation and its link to properties.

7.9.2.1. *Time–temperature profiles*

Heat-treatment time–temperature profiles for glass-ceramics may be optimized by empirical means or by performing detailed kinetic studies that provide rate constants for the reaction. Both approaches may be undertaken using either pre-treated samples or *in situ* methods. For pre-treated samples, one generally heats the starting glass rapidly, for example by inserting a specimen into a preheated furnace. After a given time period, the specimen may be extracted and analysed with the confidence that the heating rate was indeed as fast as possible.

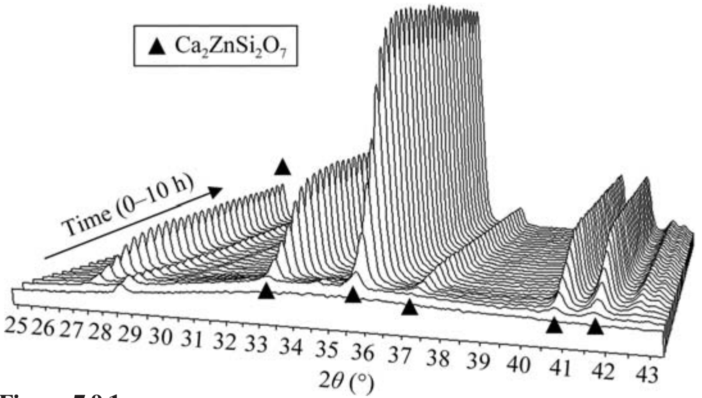

Figure 7.9.1
Three-dimensional view of isothermal *in situ* XRD data for the crystallization of $Ca_2ZnSi_2O_7$ from the glass at 1173 K.

In situ measurements provide a means of tracking crystallization as it happens, either in dynamic experiments in which the heating rate is constant or during isothermal holds. For dynamic measurements the XRD data are collected at fixed time increments while the sample continually heats or cools, and therefore obtaining a good signal-to-noise ratio can be a challenge. Modern one-dimensional detectors with remarkably fast data-collection times over small 2θ regions enable much improved experiments over point detectors. The same is of course true when comparing two-dimensional with one-dimensional detectors, with the ultimate experiment being a high-energy synchrotron experiment using two-dimensional detection. In our own laboratory, we routinely make reliable measurements in 2 s snapshots using one-dimensional detectors with sealed X-ray tube sources.

For isothermal measurements, the ideal experiment includes infinitely rapid heating to the target temperature. As noted earlier for pre-treated experiments, a good approximation to this condition is inserting the specimen into a preheated furnace. For *in situ* XRD, we may consider preheating the furnace and then inserting the sample to start the measurement. One of our own laboratory systems allows this type of measurement (Dolan *et al.*, 2003). The other option is to use the fastest heating rate possible, either in a metal strip XRD furnace or in an environmental furnace chamber. Metal strip heaters can reach the fastest heating rates, but true bulk heating furnaces may also achieve high heating rates, for example up to 600 K min^{-1} in one of our custom systems (Misture, 2003).

7.9.3. Qualitative analysis of devitrification

Qualitatively describing crystallization involves either non-isothermal or isothermal measurements of glasses defined by the following.

(i) The sample configuration: monolithic samples differ from frit or powder samples in their surface-to-bulk ratios, and therefore the extent of surface nucleation will differ among these sample configurations. Indeed, it is often straightforward to differentiate between bulk and surface nucleation using measurements of monolithic and powder samples.
(ii) The heating rate and/or the average heating rate (in the case of isothermal *in situ* measurements).
(iii) The nucleation hold time and temperature, if applicable.

Fig. 7.9.1 shows the simplest case of isothermal stoichiometric devitrification of a $Ca_2ZnSi_2O_7$ glass at 1173 K. From Fig. 7.9.1, we note that the amorphous hump that is initially present

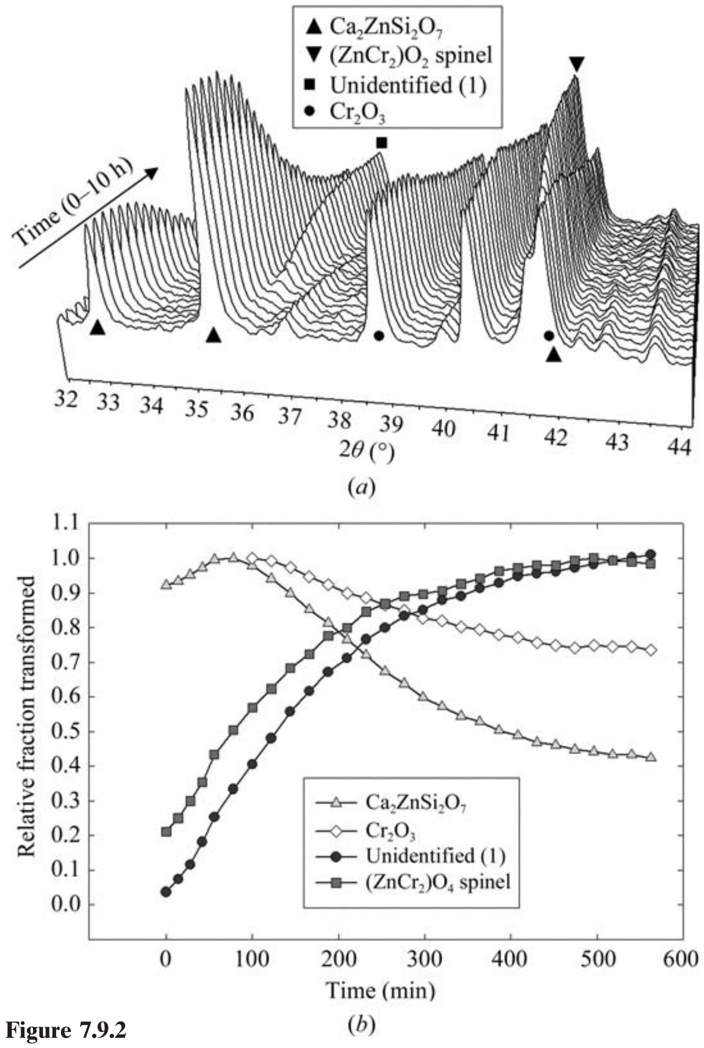

Figure 7.9.2
(*a*) *In situ* XRD isothermal data for a complex multiphase crystallization at 1223 K; (*b*) relative phase fractions of each component with time.

decreases in intensity as the crystalline $Ca_2ZnSi_2O_7$ phase grows over the course of ~200 min.

A more complex devitrification process is encountered with small changes in the initial glass composition away from $Ca_2ZnSi_2O_7$. Fig. 7.9.2 shows the *in situ* XRD data, where we note that the first XRD pattern contains peaks for $Ca_2ZnSi_2O_7$ and Cr_2O_3; in other words, these phases crystallized rapidly on heating to 1223 K. Two new phases crystallize over the course of the 10 h experiment, one of which is $ZnCr_2O_4$, which crystallizes at the expense of the $Ca_2ZnSi_2O_7$ phase. Clearly, a reaction between $Ca_2ZnSi_2O_7$ and Cr_2O_3 occurs to extract the zinc from the crystalline phase and therefore slowly eliminate the $Ca_2ZnSi_2O_7$ phase. A fourth phase begins to crystallize after about 1 h but was not successfully identified. Indeed, the issue of metastable phases in the study of glass-ceramics is of key importance, and one might expect to very often find diffraction patterns for high-temperature phases that have not been reported. It is possible in many cases to employ additional tools to identify the chemical composition of new phases and to prepare and characterize them separately. Some of our recent work has demonstrated this approach, where we have used *ab initio* structure solutions from powder-diffraction data to provide full structural data (Dolan & Misture, 2007). Of course, given the crystal structures, we can then perform Rietveld quantification to improve our analysis.

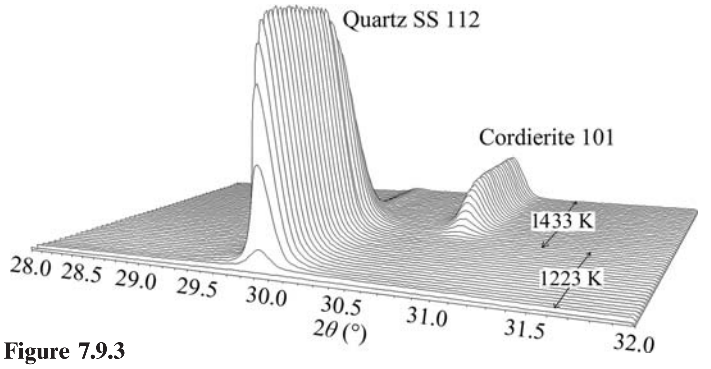

Figure 7.9.3
In situ XRD patterns for an $NiO{\cdot}MgO{\cdot}Al_2O_3{\cdot}SiO_2$ glass held isothermally at 1223 K for 1100 s to crystallize a β-quartz solid solution (SS) followed by heating to 1333 K to transform it to cordierite.

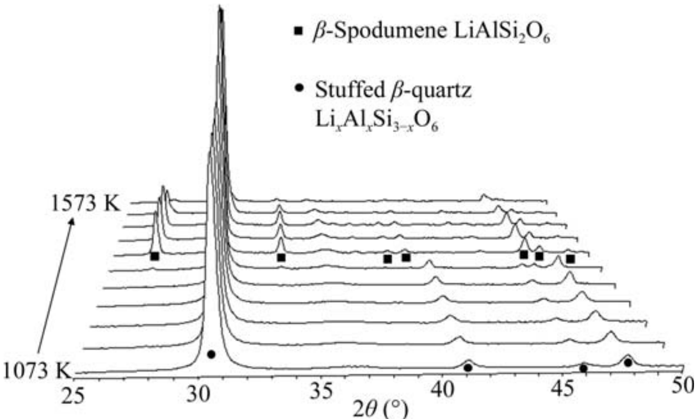

Figure 7.9.4
Example of a crystal-to-crystal conversion in Robax glass-ceramic. Temperature steps are 50 K between each XRD pattern.

Another example of the development of multiple phases is shown in Fig. 7.9.3, where we find complete conversion from β-quartz to cordierite during crystallization of $NiO{\cdot}MgO{\cdot}Al_2O_3{\cdot}SiO_2$ glasses (Miller & Misture, 2010). Fig. 7.9.3 shows the results for a sample held isothermally at 1223 K for 1100 s to crystallize β-quartz, followed by heating to 1333 K to transform the quartz to cordierite.

Finally, Fig. 7.9.4 shows an example of a crystal-to-crystal transformation. The glass is a commercial material manufactured by Schott Glass: Robax. Robax is a 'fully' crystalline glass-ceramic with a stuffed β-quartz crystalline phase, $Li_xAl_xSi_{3-x}O_6$. As shown in the *in situ* XRD patterns in Fig. 7.9.4, the β-quartz phase transforms to β-spodumene, $LiAlSi_2O_6$, near 1323 K (Sinton *et al.*, 2008). This result demonstrates the richness of options when processing glass-ceramics, where we may define the crystalline phases present by simply defining the time–temperature profile.

7.9.4. Kinetics analysis

7.9.4.1. *Theory*

The devitrification of glasses to form one or more crystalline phases is traditionally studied using the Kissinger analysis of thermal analysis heat-flow data, *i.e.* DSC or DTA. For diffraction data, we instead use the JMAK method, which is a more general approach that is easily applied. The JMAK method is named after Johnson and Mehl (Johnson & Mehl, 1939), Avrami (Avrami, 1939, 1940, 1941) and Kolmogorov (Kolmogorov, 1937), who described the isothermal transformation kinetics for nucleation and growth according to

$$x(t) = 1 - \exp(-kt^n), \qquad (7.9.1)$$

where x is the volume fraction transformed, t is the elapsed time, k is the rate constant and n is the Avrami exponent. The Avrami variables depend upon the type of nucleation and growth. For example, in the case of spherical crystals growing from homogenously distributed nuclei $k \simeq 1$ and $n = 4$ (Holand & Beall, 2002). The reader is referred to Hancock & Sharp (1971), who provide a set of ten theoretical rate equations with varied Avrami exponents as well as further detail regarding the interpretation of the Avrami exponents.

Equation (7.9.1) can be recast as $-\ln\{\ln[1 - x(t)]\} = \ln B + n\ln(t)$, and it is convenient to plot $\ln\{-\ln[1 - x(t)]\}$ *versus* $\ln(t)$ to extract the slope, n, as the Avrami exponent. The fraction transformed, $x(t)$, comes directly from the diffraction data, either using a simple measurement of peak heights or areas, or by more complex means including full absolute quantification to provide the quantity of all crystalline phases and the amorphous phase present.

To extract the fullest information from the analysis, one must measure the transformation rates at several temperatures (this is an isothermal approach) and then fit the rate constants (k) to the data in the form of an Avrami plot. Next, the rate constants can be used in an Arrhenius analysis to determine the temperature dependence of the reaction rates and therefore the activation energy for crystallization. An Arrhenius plot is typically shown as $\ln(k) = E_a/RT + \ln(A)$, where E_a is the activation energy for crystallization, R is the gas constant and A is the pre-exponential factor.

7.9.4.2. *Complexities in kinetics measurements*

From an experimental point of view, it is most common to measure changes in the XRD patterns after (or during) isothermal holds. Naturally, *post situ* XRD, optical microscopy or scanning electron microscopy (SEM) may be used to study individual samples after a specific heat treatment, but *in situ* analysis provides more information in a rapid and efficient manner. A drawback of isothermal measurements using *in situ* XRD is the uncertainty in the time = zero point, because of the finite heating rate experienced by the sample. However, this drawback is often mitigated by choosing temperatures where the extent of crystallization upon reaching the target temperature is insignificant, and hence the sample remains largely or fully amorphous to X-rays through at least the beginning of the first *in situ* XRD measurement. Therefore, the initial measurement provides a starting value for $x(t)$ that is zero or nearly zero, and/or $x(t)$ may be fitted to an exponential function to determine the fraction transformed at infinite time. Several examples follow to demonstrate the use of kinetics analysis.

7.9.4.3. *Kinetics analysis example 1: glass to single-phase crystal*

As discussed earlier, multi-component glasses may crystallize to form a single crystalline phase or multiple phases. An example of a complex glass crystallizing to form only one crystalline phase is EG9207, a sealing glass with an 'invert' composition (Dolan & Misture, 2007). Invert glasses contain a smaller fraction of network formers than other components and crystallize extensively, and in this example EG9207 contains only 25 mol% SiO_2, with 44 mol% alkaline-earth oxides, 15 mol% MgO and 16 mol% B_2O_3.

Fig. 7.9.5 shows the evolution of one of the XRD peaks for $Ba_2MgSi_2O_7$ as it crystallizes from a powdered glass (10 µm average particle size) isothermally at 1048 K. Fig. 7.9.5 shows clearly that the glass crystallizes over the course of roughly 900 s, and that measuring the XRD peak in 100 s increments is sufficient to provide 8–10 data points for the kinetics analysis.

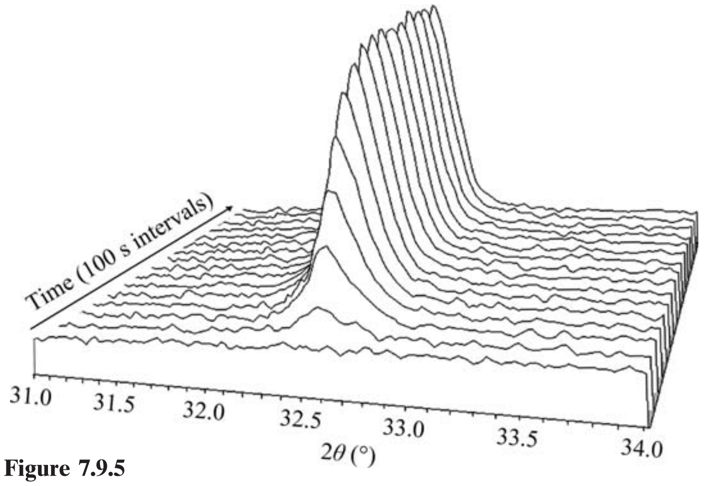

Figure 7.9.5
High-temperature XRD measurements of the crystallization of $Ba_2MgSi_2O_7$ from EG9207 glass.

Analysis of the kinetics started by extracting the peak areas from Fig. 7.9.5 and fitting an exponential function to the trend to obtain the fraction transformed, $x(t)$, *versus* time. The exponential fit provides $x(t)$ at $t \to \infty$ and is therefore a simple means of determining $x(t)$ at any t. The applicable rate equation for the process is first order, or $-\ln[1 - x(t)] = kt$. The Avrami plot is then drawn as $\ln(t)$ *versus* $\ln\{-\ln[1 - x(t)]\}$, and the slope of each Avrami plot for each isothermal measurement provides the rate constant, k. An Arrhenius plot can then be used to quantify the effects of temperature on crystallization rate, as shown in Fig. 7.9.6, the slope of which is E_a/RT, as noted earlier. For this particular glass composition, the activation energy is 281 ± 21 kJ mol^{-1}, which is typical for invert glasses (Pinckney & Beall, 2008).

Kinetics analysis provides some predictive capability and can be used to estimate the extent of crystallization at any arbitrary temperature after determining the rate constants. Fig. 7.9.7 shows the calculated crystallization rates for EG9207 glass at several temperatures, demonstrating the expected behaviour for a first-order reaction. Caution should be used, however, to ensure that extrapolations are not made beyond the bounds defined by the experimental determinations of rate constants; changes in mechanism and even additional phase transitions may occur, as shown earlier in Fig. 7.9.4.

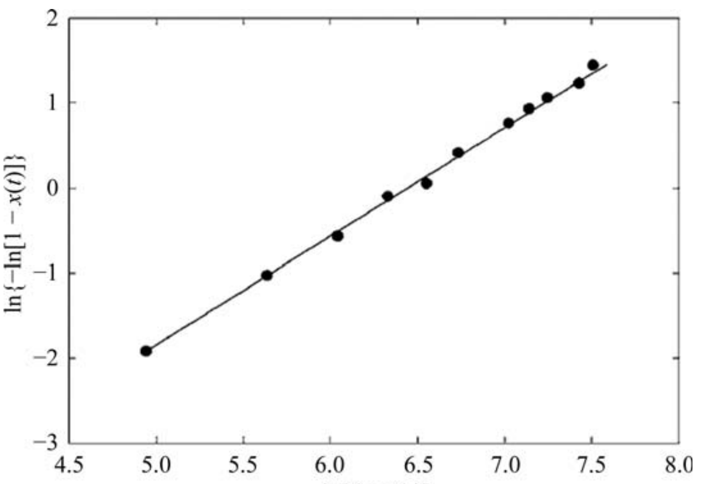

Figure 7.9.6
Avrami plot for crystallization extracted from Fig. 7.9.5.

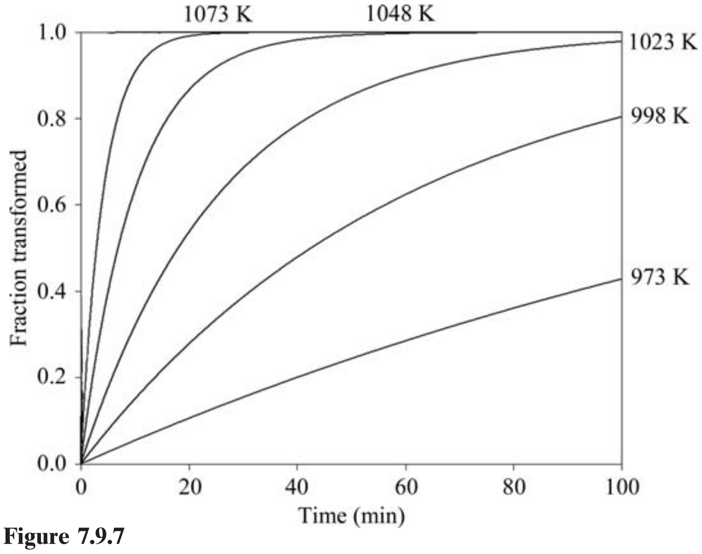

Figure 7.9.7
Crystallization rates for EG9207 glass calculated for several temperatures using the experimental rate constants.

7.9.4.4. *Kinetics analysis example 2: glass to crystal to crystal*

Extending the study shown in Fig. 7.9.3 to multiple temperatures enables full isothermal kinetics analysis of the conversion of a quartz solid solution to cordierite. The reader is referred to our complete description of the cordierite system for additional details (Miller & Misture, 2010), but in brief we show in Fig. 7.9.8 the Arrhenius plot for the crystallization of cordierite from the β-quartz phase for several glass compositions in the series. Crystallization of β-quartz occurs from the glass, and β-quartz then transforms to cordierite. The general JMAK approach allows us to directly extract the kinetics of both processes and a close examination of the reaction kinetics shows that the Avrami exponent (n value) is ~1.5 for both the glass → β-quartz and β-quartz → cordierite transformations. The value of n = 1.5 indicates that the transformation processes are diffusion-controlled with a nucleation rate of zero (Hancock & Sharp, 1971).

The initial crystallization of the glass to form β-quartz requires only ~600 kJ mol^{-1}. The activation energies calculated from the Arrhenius plot in Fig. 7.9.8 for the β-quartz → cordierite transition are between 800 and 850 kJ mol^{-1} across the compositional range, suggesting that the presence of additional nickel in the glass does not substantially change the rate-controlling steps of the reaction. Given that the Avrami exponent indicates a diffusional reaction path, we may surmise that the presence of nickel does not significantly alter the glass viscosity, density or other parameters that would affect diffusion rates.

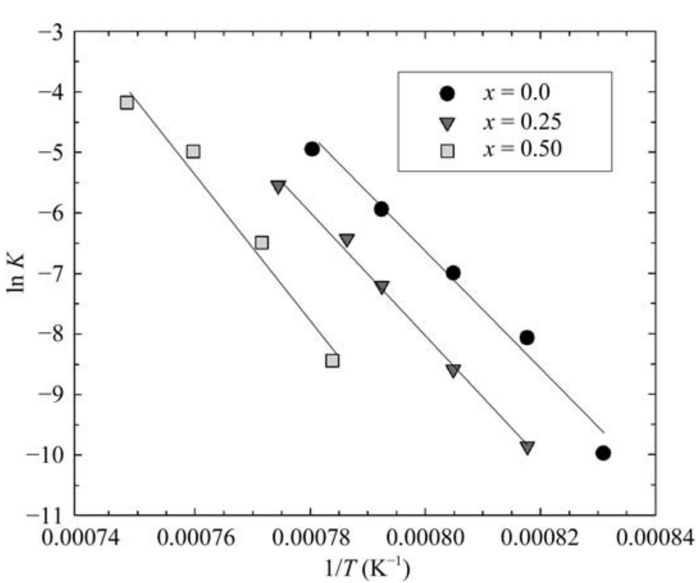

Figure 7.9.8
Arrhenius plot for the crystallization of cordierite in xNiO·(1 − x)MgO·2Al$_2$O$_3$·5SiO$_2$ glass for three different values of x. The corresponding activation energies for the transformation are 803 ± 60, 852 ± 37 and 1004 ± 117 kJ mol^{-1} for increasing values of x.

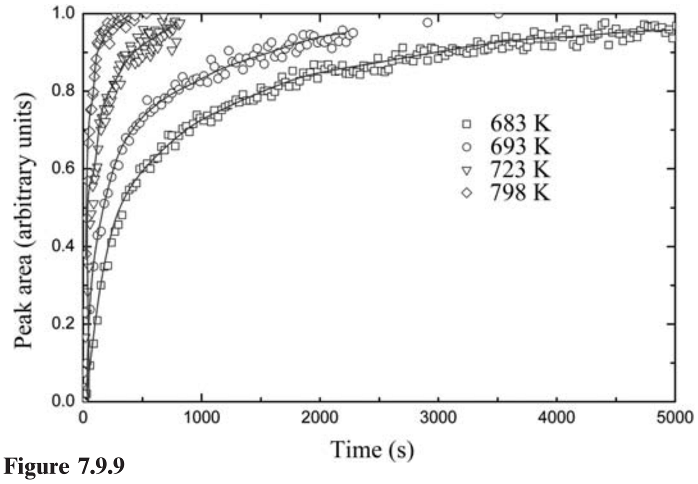

Figure 7.9.9
Reaction progress as reflected in XRD peak intensity *versus* time for the initial crystallization of 2Li$_2$O–SiO$_2$ glass.

An interesting opportunity in this reaction sequence is the ability to track the disappearance of the β-quartz phase and compare its kinetics with the kinetics of formation of cordierite. We found that the rate of disappearance of β-quartz matches the rate of growth of cordierite, confirming that the mechanism of transformation directly involves the conversion of β-quartz.

7.9.4.5. *Kinetics analysis example 3: effects of nucleation*

The final example provided relates to the nucleation treatment. Glasses of the orthosilicate composition, 2Li$_2$O–SiO$_2$, were studied using *in situ* XRD with rapid heating and data-collection rates, typically 20 s per XRD pattern (Wondraczek *et al.*, 2006). The phase progression is glass → unidentified crystalline phase (below 623 K) → Li$_4$SiO$_4$ (~773 K) → Li$_2$SiO$_3$ (~923 K). The initial crystallization is most sensitive to the nucleation treatment, and the kinetics were determined using multiple isothermal

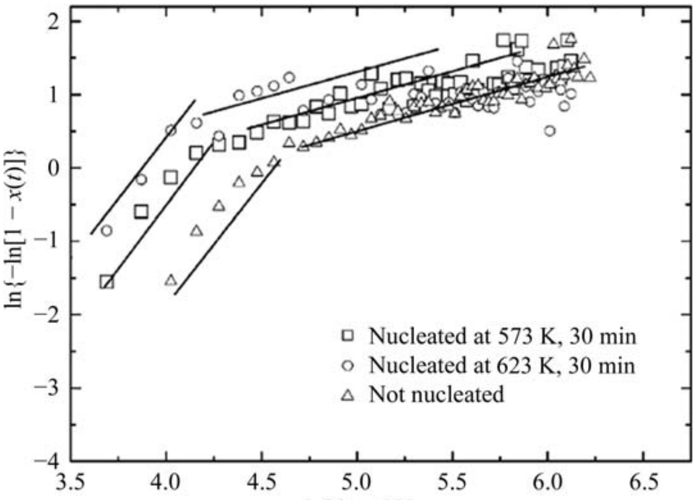

Figure 7.9.10
Effect of nucleation hold temperatures on crystallization of the glass, extracted from measurements paralleling those in Fig. 7.9.9.

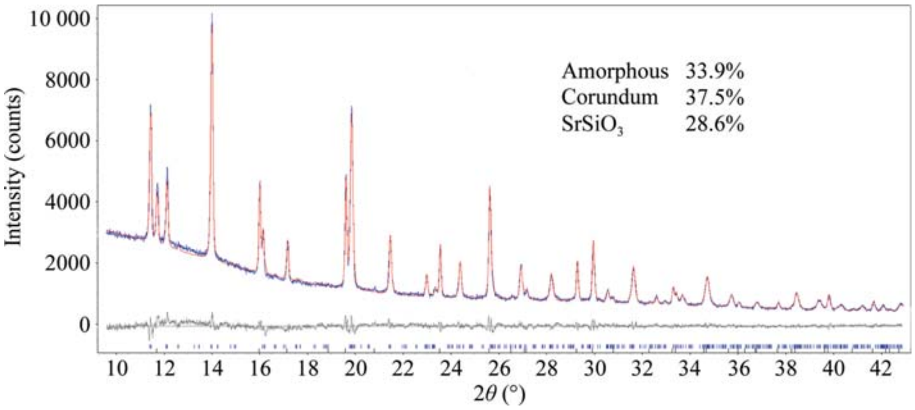

Figure 7.9.11
Rietveld fit of the XRD pattern of a partially crystallized glass, with an internal quantitative analysis standard, used to determine the remnant glass composition. Blue = observed profile, red = calculated profile, grey = difference profile.

measurements. Fig. 7.9.9 shows the growth rates which are used to generate the Arrhenius plot, yielding an activation energy of 90 kJ mol^{-1} for the transition.

To quantitatively determine the impact of nucleation, a set of nucleation experiments was performed by annealing the sample between 573 and 673 K for 30 min and then performing the isothermal high-temperature XRD experiment at 783 K. The results are shown in Fig. 7.9.10, which gives a clear indication that the extent of nucleation increases with temperature up to 623 K, which in turn increases the crystallization rate.

7.9.5. Remnant glass compositions *via* quantitative analysis

XRD has another interesting application in the area of glass-ceramics: absolute determination of the chemical composition of the remnant glass. Many glass-ceramics, in particular those used in ceramic metal sealing, rely on the complex interplay of glassy and crystalline phase components of the sealing material. In our laboratories, we have studied sealing glasses for solid oxide fuel cells extensively (Flügel *et al.*, 2007; Misture, 2008; Naylor *et al.*, 2013). In one case, for a glass containing ~60 mol% SiO$_2$, <10 mol% B$_2$O$_3$, 20 mol% SrO and 10 mol% Ga$_2$O$_3$, we found outstanding properties in the sealant, but because the sealant only crystallized to roughly 50 vol%, we endeavoured to synthesize and test the remnant glass itself.

The composition of the remnant glass phase after ~50% crystallization was determined using quantitative XRD analysis *via* the internal-standard Rietveld method. NIST SRM676 alumina quantitative analysis standard was mixed with the crystallized glass-ceramic and a powder-diffraction pattern was measured. Rietveld analysis of the pattern, shown in Fig. 7.9.11, provided the quantities of each phase (with their densities) as well as the quantity of the amorphous phase. A simple calculation then yielded the amorphous phase composition, which was prepared and tested successfully. The major crystalline phase is SrSiO$_3$, so we expected the remnant glass to be rich in boron. In fact, the original glass contained 10 mol% B$_2$O$_3$ and the remnant glass after partial crystallization was enriched to 18 mol%, markedly changing the properties of the glass.

7.9.6. Summary

Powder diffraction is a useful tool for analysis of the devitrification of glasses to form glass-ceramics. Unlike thermal-analysis methods, diffraction methods provide direct access to phase identity, phase quantities and phase-specific microstructural information, including crystallite size, microstrain and crystallite orientation. Isothermal kinetics analysis provides the crystallization activation energies and reaction rates, which are useful in the design and development of glass-ceramic preparation processes and in predicting the long-term behaviour at high temperature.

7.10. Industrial organic pigments

M. U. Schmidt

7.10.1. On organic pigments

Organic pigments are microcrystalline or nanocrystalline, coloured, highly insoluble organic compounds. There are two main chemical classes: hydrazone pigments (formerly called ‘azo pigments’) and heterocyclic pigments. Some examples are shown in Fig. 7.10.1.

Organic pigments are used industrially for the colouration of lacquers, coatings, polymers, paints, printing inks, toners, waxes *etc.* (Hunger & Schmidt, 2018). Their particle sizes are typically between 50 and 500 nm. In the application media, *e.g.* polymers, the pigments are not dissolved, but are finely dispersed. Thus, their crystal structures are maintained. At least 80% of industrially produced organic pigments are polymorphic, with most pigments having between three and six polymorphs. The number of polymorphic forms is as high as 11 for copper phthalocyanine, which is the most important pigment for blue shades in most applications. Five of the 11 polymorphs are industrially produced (*cf.* Fig. 7.10.3; Erk, 2012).

The polymorphic form depends on the conditions during synthesis, precipitation or crystallization. Additionally, the phase may change during heating as a dry powder, heating in suspension, solvent treatment, milling and storage.

(*f*) R = Cl: Pigment Violet 30

(*g*) Quinacridonequinone

Figure 7.10.1
Molecular formulae of some organic pigments mentioned in the text. Compounds (*a*)–(*c*) are hydrazone pigments.

As for inorganic pigments, the properties of organic pigments strongly depend on their crystal structures. For example, the bishydrazone compound Pigment Orange 72 (Fig. 7.10.1*a*) exhibits a red α-phase, an orange β-phase and dark brown γ- and δ-phases. Perylene pigments (Fig. 7.10.2*a*), which differ only in the lengths of the terminal alkyl or aryl chain, span the colour range from orange *via* red to black (Klebe *et al.*, 1989; Mizuguchi *et al.*, 2006). The crystal structure also has a strong effect on other properties such as thermal stability, photostability, fastness to solvents and colour strength (extinction coefficient). X-ray powder diffraction is routinely used for qualitative and quantitative phase analyses in research, development and quality control, as well as for resolving patent issues (see Section 7.10.2.1).

The particle size, the domain size, the lattice strain and the number and type of defects also have a strong influence on the properties of the pigment. For example, increasing the particle size of a yellow pigment leads to a pigment with a more orange hue, with reduced transparency and with improved hiding power, insolubility, photostability and heat fastness, but with a reduced molar colour strength. Reducing the particle size and/or increasing the number of lattice defects, *e.g.* by milling, leads to a deterioration in pigment fastness. X-ray powder diffraction is used to determine the domain size. The crystal structures of

Copyright © 2019 International Union of Crystallography

organic pigments are usually highly anisotropic because they consist of generally planar, large molecules, which tend to arrange in chains, layers or stacks. Correspondingly, the particle morphology and the domain size can be strongly anisotropic as well.

Considerable effort has been invested in determining pigment crystal structures and in understanding their structure–property relationships. The growth of single crystals is generally hampered by the insolubility of the pigments in water and most solvents, even at elevated temperatures (373–573 K). Melting results in decomposition. Sublimation is only possible for some pigments (see, for example, Mizuguchi *et al.*, 2005; Senju *et al.*, 2005). Consequently, many of their crystal structures are determined by X-ray powder diffraction. Since pigment-producing companies were highly interested in obtaining knowledge of the crystal structures of pigments which had been produced for decades, industrial organic pigments were among the first organic crystal structures to be determined from powder data. The structures of several perylene compounds (Fig. 7.10.2*a*) and of an isoindoline pigment (Fig. 7.10.2*b*) were determined in about 1995 at BASF (Erk, 1995; Erk *et al.*, 2004), that of a diketopyrrolopyrrole derivative (Fig. 7.10.2*c*) in cooperation with Ciba–Geigy in 1996 (MacLean *et al.*, 2000), and that of the $\alpha^{\rm I}$-phase of quinacridone (Fig. 7.10.1*d*) and of a series of diaryl pigments (Fig. 7.10.2*d*) at Hoechst during 1994–1996 (Leusen, 1994; Schmidt, 1996; Paulus *et al.*, 2007; Schmidt, Dinnebier & Kalkhof, 2007). Many other structures have followed since then (see, for example, Schmidt & Dinnebier, 1999; Yatsenko *et al.*, 2001; Erk & Hengelsberg, 2003; Erk *et al.*, 2004; Schmidt *et al.*, 2005, 2006; Pidcock *et al.*, 2007; Schmidt, Brüning *et al.*, 2007; Schmidt, Buchsbaum *et al.*, 2007; Schmidt & Buchsbaum, 2008; Brüning *et al.*, 2009; Schmidt, Brühne *et al.*, 2009; Ivashevskaya *et al.*, 2009; Schmidt, van de Streek & Ivashevskaya, 2009; van de Streek *et al.*, 2009; Buchsbaum *et al.*, 2011; Bekö *et al.*, 2012; Gumbert *et al.*, 2016).

A considerable number of industrial pigments are nanocrystalline and have domain sizes below 20 nm, causing very broad reflections in the X-ray powder pattern. This is especially true for pigments synthesized by azo coupling in water because the pigments are fully insoluble in water and precipitate instantaneously during synthesis as fine, nanocrystalline powders.

Several pigments do not show Bragg peaks at all. In these instances, the local structure can be investigated using pair-distribution function analysis (see Chapter 5.7).

7.10.2. Main applications of X-ray powder diffraction to organic pigments (and other organic compounds)

The main applications are as follows.

(i) Qualitative phase analysis.
(ii) Quantitative phase analysis.
(iii) Determination of the domain size.
(iv) Structure determination from powder-diffraction data.
(v) Determination of the amorphous content.
(vi) Investigation of the local structures of nanocrystalline and amorphous organic compounds using pair-distribution function analyses.

For all applications, the X-ray powder diffractograms (also called 'powder patterns') should be measured in transmission mode in order to minimize preferred-orientation effects. The sample can be placed between polymer films or enclosed in a capillary. Usually, the diffractograms are measured using Cu $K\alpha_1$ radiation. A shorter wavelength is preferred for pair-distribution function (PDF) analyses in order to increase the resolution of the PDF curve.

7.10.2.1. *Qualitative phase analysis*

Qualitative phase analysis is used to identify the crystalline phases in a sample. The identification is generally made by comparison of the powder pattern to simulated or experimental X-ray powder patterns of known phases, or by a search in databases such as the Powder Diffraction File (Fawcett *et al.*, 2017). The phase analysis can also be performed in suspension, or in the final application, for example in coatings, if the pigment content is sufficiently high.

Applications include the following.

(i) The identification of polymorphic forms. Since the properties of the pigments strongly depend on the polymorphic form, it is essential to know which polymorphic forms are present in a given sample (Fig. 7.10.3). For the identification of polymorphs, X-ray powder diffraction is generally much more reliable and more sensitive than thermal methods or spectroscopic methods such as infrared or solid-state NMR spectroscopy. Qualitative phase analysis by X-ray diffraction is a routine tool in pigment research, development and quality control.
(ii) The identification of crystalline by-products and admixtures, *e.g.* other pigments or extenders such as $BaSO_4$.
(iii) The identification of pigments, for example in forensic investigations (see, for example, Curry *et al.*, 1982).
(iv) The identification of solid solutions. A mixture of chemically similar pigment molecules frequently crystallizes as a solid solution (mixed crystal) instead of forming a physical mixture of the crystals of the individual compounds. Such solid solutions may also exist in different polymorphic forms (Schmidt, Kempter *et al.*, 2002). The X-ray powder pattern of a physical mixture is the sum of the powder patterns of the

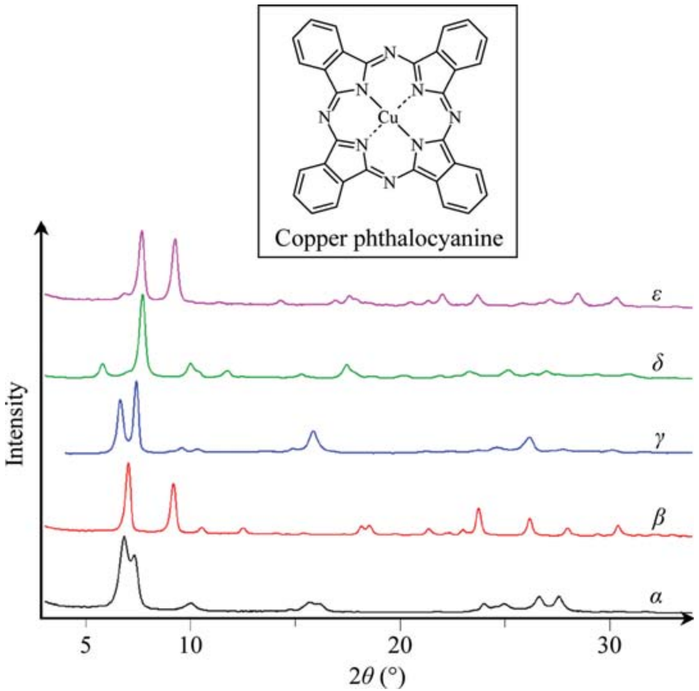

Figure 7.10.3
X-ray powder patterns of five polymorphs of copper phthalocyanine (Pigment Blue 15), which is the most important blue pigment. All five polymorphs are industrially produced. The patterns were recorded with Cu $K\alpha_1$ radiation. This book is printed with copper phthalocyanine (β-phase).

individual compounds, whereas a solid solution has a different powder pattern, with at least modified reflection positions and intensities. Several industrial pigments are sold as solid solutions, *e.g.* consisting of quinacridone and its methylated or chlorinated derivatives (Figs. 7.10.1*d* and 7.10.1*e* or Figs. 7.10.1*d* and 7.10.1*f*), or quinacridone and quinacridonequinone (Figs. 7.10.1*d* and 7.10.1*g*) (Hunger & Schmidt, 2018).

(v) The description of polymorphic forms in patents.

New polymorphic and pseudopolymorphic forms can be protected by patents. Patents are filed especially if the new crystal phases exhibit improved properties, for example for pigments with different shades or improved photostability, pharmaceuticals with improved bioavailability or better storage stability, or industrial intermediates with improved processability.

There are several industrial pigments which were or are protected only by patents on the polymorphic form, while the patent on the compound itself has expired. Examples include the γ-phase of Pigment Red 170 (Fig. 7.10.1*b*, Ribka, 1972) and the β-phase of Pigment Yellow 191 (Fig. 7.10.1*c*, Schmidt, Acs *et al.*, 2002). Similarly, many active pharmaceutical ingredients are protected for several additional years only by patents on their polymorphic form (Bernstein, 2007; see also Chapter 7.5).

A patent on a new polymorph usually contains either a figure showing the X-ray powder pattern or a listing of the characteristic reflections. However, powder data from patents should be regarded with caution. The data may be strongly affected by texture effects or by preferred orientation (expecially if the data are recorded in reflection mode). The pattern may display a mixture of polymorphs. It may contain reflections of organic or inorganic by-products, or even reflections arising from the sample holder. Lines may be shifted owing to measurement errors or owing to the formation of solid solutions *etc.* A given phase may be patented several times under different names, with different domain sizes or with different amounts of by-products, or a given phase name (*e.g.* 'phase III') may correspond to different polymorphs. An illustrative example for such 'phase chaos' is quinacridone (Fig. 7.10.1*d*). In the patent literature at least 14 phases are mentioned, which are called α, β, $\beta_{\rm I}$, γ, γ', $\gamma^{\rm I}$, $\gamma^{\rm II}$, $\gamma^{\rm III}$, $\gamma^{\rm IV}$, δ, Δ, two different ε-phases and at least one ζ-phase (Struve, 1958; Reidinger & Struve, 1958; Manger & Struve, 1958; Deuschel *et al.*, 1963; Schweizer, 1966; Hashizume *et al.*, 1970; Tyson & Schapiro, 1975; Toyo, 1976; Jaffe, 1988, 1989; Bäbler & Jaffe, 1993; Bäbler, 2001). All of the phases were characterized by X-ray powder diffraction. A closer look at the powder data for the individual phases reveals that β and $\beta_{\rm I}$ actually describe identical phases, and all of the γ-phases belong to only one crystallographic phase (γ). The phases described as 'δ' are either equivalent to the γ-phase or consist of a mixture of the γ-phase with a trace of the β-phase. Furthermore, the Δ-phase is the same polymorph as the γ-phase. The two ε-phases are actually both the γ-phase. The ζ-phase is apparently a mixture of at least three different phases (α, β and γ). To add to the confusion, the name 'α-phase' is actually used for two different phases, $\alpha^{\rm I}$ and $\alpha^{\rm II}$, which differ considerably from each other in their colours and in their X-ray powder patterns. Hence, a total of four phases remain ($\alpha^{\rm I}$, $\alpha^{\rm II}$, β and γ). For a review, see Paulus *et al.* (2007).

7.10.2.2. *Quantitative phase analysis*

Quantitative phase analysis is frequently used to determine the amounts of different polymorphic forms in a pigment sample. Applications include the following.

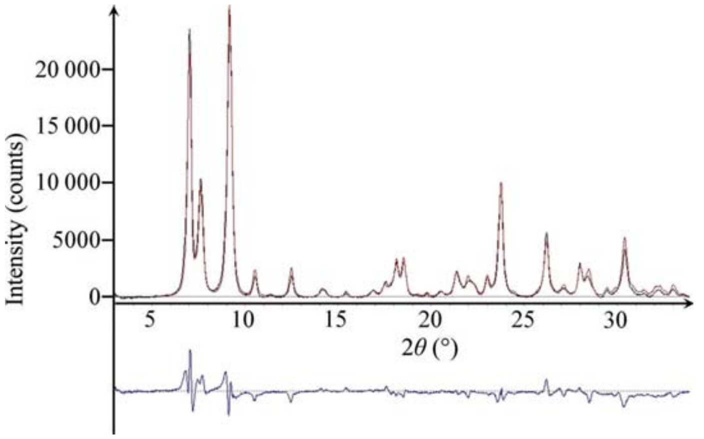

Figure 7.10.4
Quantitative phase analysis of a 70:30 mixture of the β- and the ε-phases of copper phthalocyanine (Pigment Blue 15) using the program *SiroQuant*. The data were measured with Cu $K\alpha_1$ radiation in transmission mode on a STOE Stadi-P diffractometer. The calculated ratio of the phases is 70.6 (±1.2)% β to 29.4 (±1.2)% ε. Courtesy of Martin Ermrich, Röntgenlabor Dr Ermrich, Reinheim, Germany.

(i) Optimization of synthesis and crystallization.
(ii) Quality control in production, especially for those pigments that are sold as a mixture of polymorphs.
(iii) Patent issues.

Quantitative phase analysis is additionally used for the quantification of different chemical entities in a mixture.

The methods for quantitative phase analysis are described in Chapter 3.9. The main methods used for organic pigments are as follows.

(i) Visual inspection of the diffraction pattern and comparison with reference patterns of mixtures with known composition.
(ii) Evaluation of the intensities of one or several non-overlapping reflections.
(iii) Quantitative Rietveld refinement.

The reliable quantitative phase analysis of organic pigments is frequently challenging because the small domain sizes result in broad reflections with high peak overlap. Additionally, most crystal structures are unknown; thus, is it not possible to simulate the powder patterns from single-crystal data. Furthermore, anisotropic peak broadening and texture effects have an influence on the powder pattern. Therefore, the use of a mixture series of the individual polymorphs to prove (and calibrate, if necessary) the results of a Rietveld refinement is generally recommended.

Most Rietveld programs can be used for quantitative phase analysis. Some programs, such as *SiroQuant* (Sietronics, 2013), are specially designed for phase quantification.

Fig. 7.10.4 shows an example of a quantitative Rietveld refinement using *SiroQuant*. The sample consisted of a 70:30 mixture of the β- and ε-phases of copper phthalocyanine. Powder patterns of the individual phases are shown in Fig. 7.10.3. All data were measured in transmission mode with Cu $K\alpha_1$ radiation on a STOE Stadi-P diffractometer. The crystal structural data were obtained from the Cambridge Structural Database (Groom *et al.*, 2016) [Refcode CUPOCY10 (Brown, 1968) and Refcode CUPOCY16 (Erk *et al.*, 2004)]. After background corrections, only the scale factors, lattice parameters, domain sizes and parameters for preferred orientation were refined. The atomic coordinates were left unchanged. Quantification was successful despite the broad peak widths of the sample. The Rietveld refinement calculates amounts of 70.6 and 29.4 (±1.2)% for the β

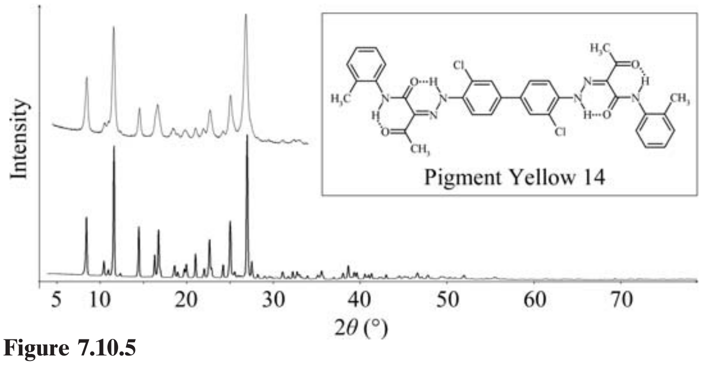

Figure 7.10.5
The effect of different domain sizes of Pigment Yellow 14. Top, the industrial product used in printing applications, with a domain size of about 40 nm. Bottom, sample recrystallized from dichlorobenzene at 453 K, with a domain size of about 500 nm. The data are laboratory data measured with Cu $K\alpha_1$ radiation in transmission mode on a STOE Stadi-P diffractometer.

and the ε modifications, respectively (R = 0.167). The domain sizes of the two phases were refined to τ = 65 nm for the β modification and τ = 52 nm for the ε modification.

7.10.2.3. *Determination of the domain size*

The widths and the shapes of the diffraction peaks in a powder pattern contain information on the domain sizes, on the lattice strain and on the number and type of defects. All features can be highly anisotropic. Industrial organic pigments generally have limited domain sizes, resulting in quite broad reflections. (This is especially true for the transparent pigments used in printing applications.) Typically, the domain sizes are between 20 and 100 nm (Fig. 7.10.5). In most cases, the data quality does not allow a separate determination of domain size, lattice strain and lattice defects. Often only the domain size is determined, which is regarded as a measure of the 'crystal quality' of the sample. (Frequently, the term 'crystallinity' is used to describe the domain size and/or the crystal quality. However, 'crystallinity' refers to the ratio of crystalline to amorphous content in a sample.) The domain size can either be calculated from the widths of individual non-overlapping reflections using the Scherrer formula (Chapter 5.1) or from the full profile using LeBail, Pawley or Rietveld refinements.

7.10.2.4. *Structure determination from powder-diffraction data*

7.10.2.4.1. *Procedure*

The information content of an X-ray powder pattern is limited, especially in the instance of poorly crystalline organic pigments. To compensate for this, the molecular geometry is used as additional information. An approximated or assumed molecular geometry is sufficient if the molecular flexibility, in particular torsions around single bonds, is taken into account. Further information could be provided by electron diffraction, solid-state NMR, IR or Raman spectroscopy.

The standard procedure for the determination of crystal structures of organic pigments and other molecular compounds from X-ray powder data consists of the following five steps.

(i) Measurement of a high-quality X-ray powder diffractogram in transmission mode.
(ii) Determination of reflection positions; indexing and determination of possible space groups.
(iii) Extraction of reflection intensities.
(iv) Structure solution, for example by real-space methods (see Chapter 4.3).
(v) Rietveld refinement.

The third step (extraction of reflection intensities) is crucial if the structure is to be solved by direct methods or charge flipping, but may be skipped in the case of real-space methods. Nevertheless, some real-space methods, such as *DASH* (David *et al.*, 2006), perform an extraction of reflection intensities to increase the calculation speed.

The most problematic step is still the indexing, *i.e.* the determination of the lattice parameters from the peak positions. The indexing fails if the powder has domain sizes that are too small or if it contains a mixture of different phases. In these cases the following approaches can be used.

(i) Modification of the syntheses and the crystallization conditions in order to obtain a single-phase powder and/or a powder with improved domain sizes.
(ii) Determination of the lattice parameters by electron diffraction (Gorelik *et al.*, 2009; Schmidt, Brühne *et al.*, 2009).
(iii) Searching for an isostructural derivative with improved domain sizes or known structure.
(iv) The prediction of possible crystal structures by global lattice-energy minimizations with free lattice parameters in various space groups. The minimizations can be performed by force-field or quantum-mechanical methods, or by combinations of these (Neumann *et al.*, 2008; Day *et al.*, 2009; Mörschel & Schmidt, 2014). In order to determine which of the predicted structures corresponds to the actual phase, the diffraction patterns are simulated for all low-energy structures and compared with the experimental pattern.

In difficult cases approaches (i)–(iv) have to be combined.

In all cases the structure is finally refined by the Rietveld method. Rietveld refinement also allows the location of missing atoms, *e.g.* counter-ions, water or solvent molecules. Generally, rigid bodies, constraints or restraints on the molecular geometry are applied in order to avoid chemically meaningless distortions of the molecules. Finally, if the quality of the data is good enough, a refinement of all atomic positions without restraints (except for H atoms) should be tried; if the atoms move only slightly, the structure can be considered to be correct. Alternatively, the correctness of the crystal structure can be proven by a quantum-mechanical lattice-energy minimization with a free unit cell (van de Streek & Neumann, 2014).

7.10.2.4.2. *Examples*

7.10.2.4.2.1. Pigment Red 57:1

Pigment Red 57:1 (Fig. 7.10.6) is used worldwide for printing newspapers, journals and books. This book is also printed with the β-phase of Pigment Red 57:1. The crystal structure of the α-phase (trihydrate) of Pigment Red 57:1 was solved by real-space methods from laboratory data measured in transmission mode (Bekö *et al.*, 2012). After indexing, the structure was solved with *DASH* (David *et al.*, 2006). The real-space search was performed with a flexible molecule, the counter-ion and two of the three water molecules, leading to in total 18 degrees of freedom. The third water molecule was located during the Rietveld refinement. Rietveld refinements were carried out with *TOPAS* (Coelho, 2018) using restraints on bond lengths, bond angles and planar groups. The refinement converged with a smooth difference curve (Fig. 7.10.6). In the same way, the crystal structures of the β-phase (monohydrate) and the γ-phase

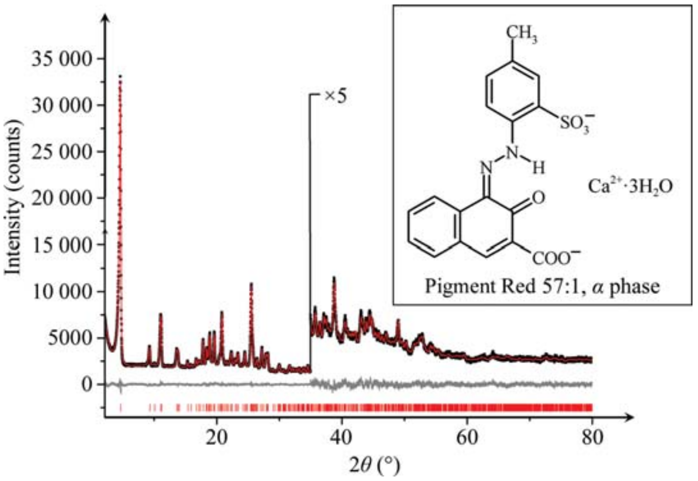

Figure 7.10.6
Rietveld refinement of Pigment Red 57:1 (α-phase, trihydrate). The experimental pattern is drawn as points and the calculated pattern as a solid line; the difference curve is shown at the bottom, with reflection positions as vertical lines. The data are laboratory data measured with Cu $K\alpha_1$ radiation in transmission mode on a STOE Stadi-P diffractometer. The space group is $P2_1/c$ with $Z = 4$, $a = 8.7613$ (5), $b = 5.8155$ (3), $c = 37.943$ (2) Å, $\beta = 90.883$ (3)°. R values: $R_{\rm wp} = 3.13\%$, $R_{\rm p} = 2.38\%$, $R_{\rm exp} = 2.48\%$ (values before background subtraction), $R'_{\rm wp} = 8.66\%$, $R'_{\rm p} = 7.89\%$, $R'_{\rm exp} = 6.85\%$ (after background subtraction); $\chi^2 = 1.264$.

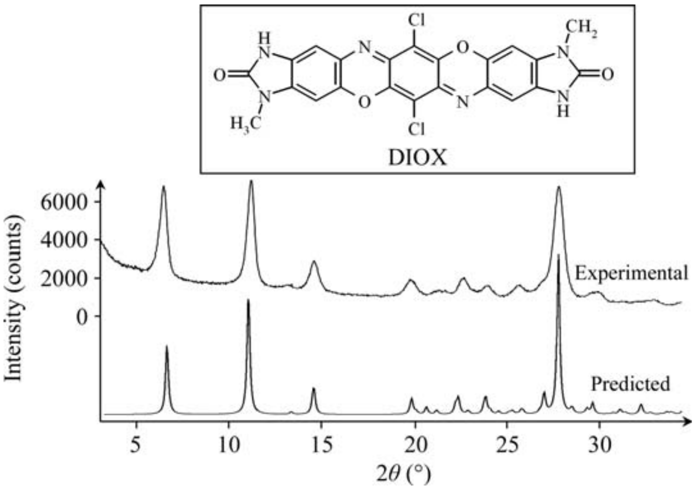

Figure 7.10.7
Structure solution of the nanocrystalline pigment DIOX. Top, experimental X-ray powder pattern (Cu $K\alpha_1$ radiation); bottom, simulated pattern of the predicted structure with energy rank 5, without any fit to the experimental data. The space group is $P\bar{1}$ with $Z = 1$, $a = 4.335$, $b = 8.419$, $c = 13.906$ Å, $\alpha = 106.95$, $\beta = 92.91$, $\gamma = 95.12°$, $V = 481.9$ Å^3. The difference between the simulated and experimental patterns is as small as for a misorientation of the molecule of about 1°.

(anhydrate) were determined. All three phases exhibit a double-layer structure, as is frequently observed in ionic molecular crystals. The nonpolar layer is formed by the phenyl and naphthalene fragments, whereas the polar/ionic layer contains the Ca^{2+} ions and the SO_3^-, COO^- and C=O groups, as well as the water molecules. Moisture-dependent and temperature-dependent X-ray powder diffraction investigations revealed that all phases can interconvert, depending on the temperature and relative humidity. These phase changes may result in a shift in the shade of red in printed newspapers depending on the weather conditions.

7.10.2.4.2.2. *Dioxazine pigment*

Crystal-structure predictions by lattice-energy minimizations were necessary to solve the structure of the nanocrystalline violet dioxazine pigment DIOX (Fig. 7.10.7). The compound is completely insoluble in water and all other solvents. Even in the best available solvents such as *N*-methylpyrrolidone or DMSO the solubility at about 473 K is below the detection limit of 10 µg l^{-1}. Correspondingly, all attempts at recrystallization failed. Sublimation was possible at 10^{-3} mbar (1 mbar = 100 Pa) and 623 K, but did not result in improved crystallinity. The best powder pattern of the β-phase is shown in Fig. 7.10.7 (top). From the line widths, a domain size of about 20 nm can be estimated. None of the powder patterns could be indexed. Possible crystal structures were predicted with the program *CRYSCA* (Schmidt & Kalkhof, 1997), starting from a very large set of random packings in various space groups with free lattice parameters. The lattice energy was optimized for all structures. After removing duplicate structures, X-ray powder diagrams were simulated for all low-energy structures and were compared with the experimental diagram. The packing with energy rank 5 showed a simulated powder diagram that was quite close to the experimental one (Fig. 7.10.7, bottom), indicating that this structure is very close to correct. The Rietveld refinement was challenging because the reflections were extremely broad. The correctness of the structure was finally proven some years later *via* the structure determination of an isostructural phase: if 50% of the CH_3 groups are replaced by C_2H_5 groups, a solid solution of CH_3 and C_2H_5 derivatives is formed. This solid solution exhibited excellent crystallinity. Its structure could be solved and refined without problems and confirmed the structure of the methyl derivative (Schmidt *et al.*, 2005).

7.10.2.4.2.3. *Pigment Red 170*

The structure of the nanocrystalline α-phase of Pigment Red 170 was solved *via* the crystal structure of an isostuctural methyl derivative with better crystallinity (Fig. 7.10.8). Indexing the powder pattern of the methyl derivative yielded the lattice parameters a^*, b^* and γ^*. Since 30 out of 33 low-angle reflections could be indexed with $hk0$, insufficient information was available to determine the remaining parameters c^*, α^* and β^*. The crystal system and the space group also remained unknown. The structure of the methyl derivative was solved by crystal-structure predictions in various space groups using the program *FlexCryst* (Hofmann & Apostolakis, 2003). Subsequently, the structure was refined against synchrotron data using the program *GSAS* (Larson & Von Dreele, 1994). The resulting structure of the methyl derivative was used as a starting model to refine the crystal structure of Pigment Red 170 from laboratory data (Schmidt *et al.*, 2006).

7.10.2.5. *Determination of the amorphous content*

A few organic pigments are sold as amorphous powders, which show no Bragg peaks in their X-ray powder diffractograms. Some other pigments are crystalline, but contain amorphous additives or extenders; for example, pigments used in offset printing can contain up to 30% of resin (which improves the dispersibility). The amorphous content in a sample can be analysed by different methods. The accuracy is generally improved by a calibration curve using mixtures of amorphous and crystalline compounds.

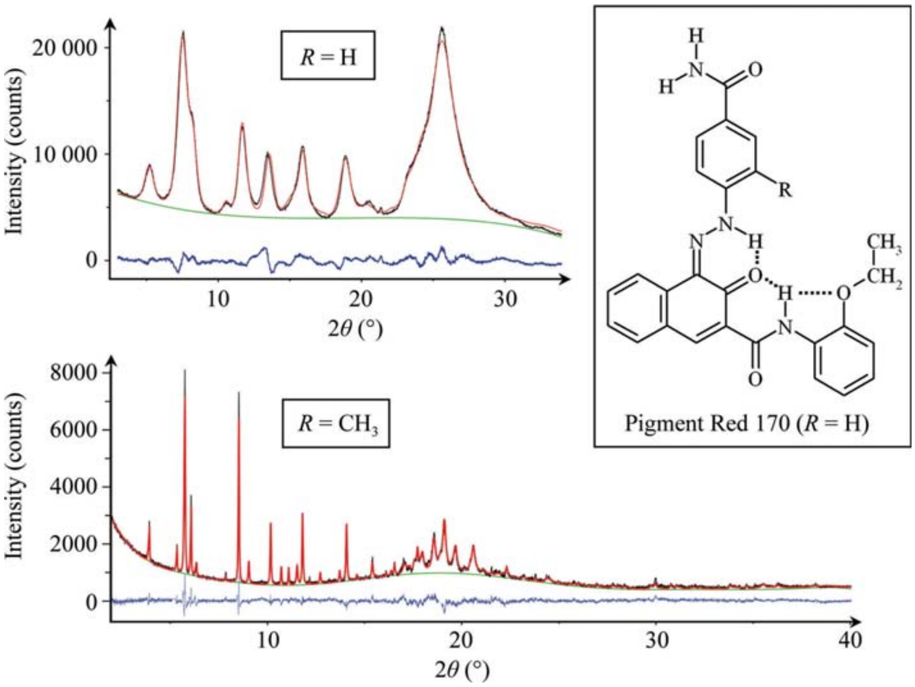

Figure 7.10.8

Structure determination of the nanocrystalline α-phase of Pigment Red 170 from powder data using an isostructural methyl derivative with improved crystallinity. Top, Rietveld plot of the α-phase of Pigment Red 170 (R = H); bottom, methyl derivative (R = CH_3). Experimental diffractograms are in black, the calculated diffractogram is in red, the background is in green and difference curves are in blue. Wavelengths were 1.5406 Å (Cu $K\alpha_1$) for Pigment Red 170 and 1.149914 Å (synchrotron radiation) for the methyl derivative. The space group is $P2_12_12_1$, with Z = 4, a = 23.960 (9), b = 23.234 (9), c = 3.887 (1) Å for Pigment Red 170 and a = 24.6208 (9), b = 22.8877 (9), c = 3.9388 (2) Å for the methyl derivative.

7.10.2.6. *Investigation of local structures of nanocrystalline and amorphous organic compounds using pair-distribution function analyses*

7.10.2.6.1. *General*

There is no sharp boundary between crystalline, nanocrystalline and amorphous states. In an amorphous sample the molecules can be ordered, despite the absence of Bragg reflections. For example, an organic compound with a domain size of 10 nm corresponding to about 5 × 5 × 5 unit cells with 500 molecules will not cause a single visible peak in the X-ray powder pattern; nevertheless, the molecules have a given conformation and form an ordered arrangement with a defined local structure.

Local structures in crystalline, nanocrystalline and amorphous organic compounds, including pharmaceuticals, agrochemicals, pigments and optoelectronic materials, can be investigated by pair-distribution function (PDF) analysis.

The pair-distribution function (also called the 'radial distribution function') represents the probability $G(r)$ of finding two atoms with an interatomic distance r. The PDF is weighted with the scattering power of the two atoms and is summed over all atom–atom pairs. The PDF contains intramolecular as well as intermolecular atom–atom distances. PDF curves are derived by Fourier transformations from carefully measured powder diffractograms. The method itself is explained in Chapter 5.7.

Applications to organic compounds include the following.

(i) The investigation of local structures and packing motifs in nanocrystalline and amorphous compounds.

(ii) The identification of polymorphic forms in nanocrystalline and amorphous compounds.

(iii) The investigation of the actual atomic and molecular arrangements in disordered structures.

(iv) To determine whether a powder is a co-crystal or a physical mixture of the individual compounds.

(v) The detection of crystal seeds in an amorphous powder. The commencement of crystallization is visible in the PDF at an earlier stage than in the powder diagram itself.

PDF analyses are widely used for inorganic compounds, for example glasses, liquids, amorphous or highly disordered materials, quasicrystals *etc.* (Neder & Proffen, 2009; Egami & Billinge, 2012). The application of PDF methods to organic compounds is at present (2018) in its infancy. The generation of a PDF curve from powder diffraction data is possible with programs such as *PDFgetX3* (Juhás *et al.*, 2013). The simulation of PDF curves from a structural model can be achieved, for example with *DISCUS* (Neder & Proffen, 2009), *RMCprofile* (Tucker *et al.*, 2007), *PDFgui* (Farrow *et al.*, 2007), *DiffPy-CMI* (Juhás *et al.*, 2015) or *TOPAS* (Coelho, 2018) (see Fig. 7.10.9). The full fitting of a structural model of an organic crystal structure to a PDF curve using restraints for bond lengths, bond angles and planar groups, such as in a Rietveld refinement, is nowadays becoming possible (Prill *et al.*, 2016).

7.10.2.6.2. *Example: nanocrystalline phase of Pigment Yellow 213*

Pigment Yellow 213 is an industrial hydrazone pigment used for automotive coatings. The compound exhibits two polymorphs (Fig. 7.10.10). The brown β-phase is obtained directly from the synthesis. Solvent treatment for 3 h at 423 K leads to the desired greenish-yellow α-phase. The crystal structure of the α-phase could be solved by a combination of X-ray powder diffraction, electron diffraction and lattice-energy minimizations (Schmidt, Brühne *et al.*, 2009). The molecules are almost planar and form a layer structure with an interlayer distance of 3.3 Å (Fig. 7.10.11).

The metastable β-phase is a nanocrystalline powder. The structures of both phases were investigated by PDF analyses. Powder patterns were carefully recorded with a short wavelength

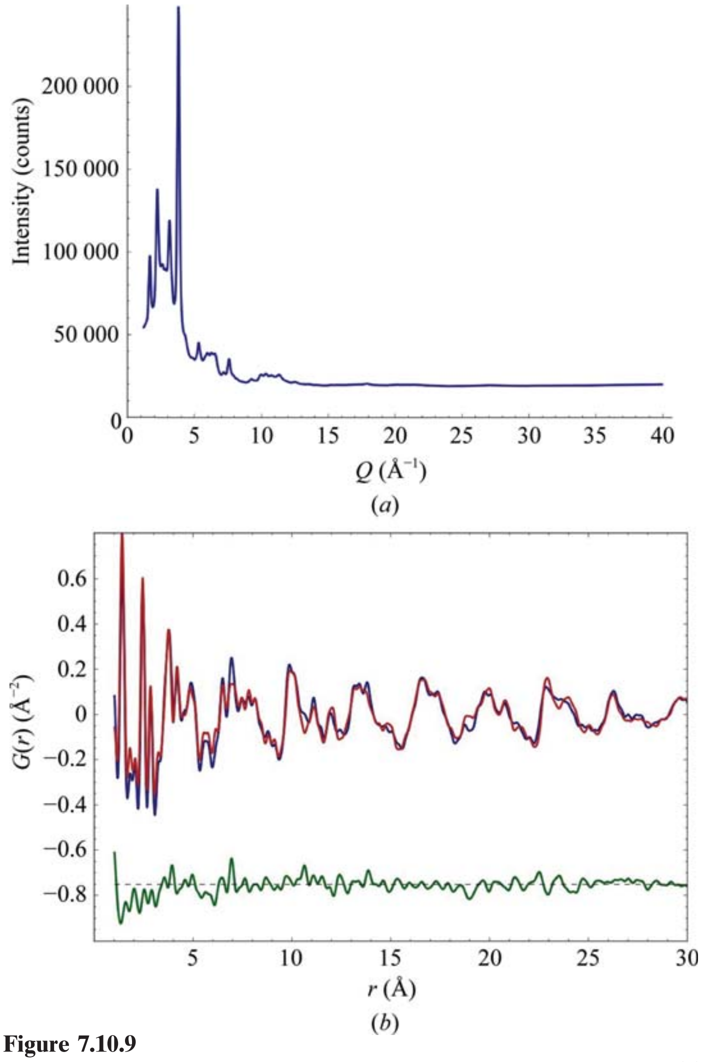

Figure 7.10.9
Pair-distribution function analyses of the β-phase of quinacridone. (*a*) Synchrotron X-ray powder pattern after normalization; λ = 0.2128 Å. (*b*) Comparison of the experimental PDF curve ($Q_{\max}$ = 19 Å^{-1}, blue) and the PDF simulated from the crystal-structure data (red). The difference curve is shown in green. The peak width was fitted with two parameters ($B_{\rm iso}^{\rm mol}$, $B_{\rm iso}^{\rm cryst}$) using the program *DiffPy-CMI*. The lattice parameters were refined. The atomic coordinates were not modified (Prill *et al.*, 2016). Note that the PDF curve is normalized in such a way that a value of $G(r)$ = 0 indicates an average probability, not a probability of zero.

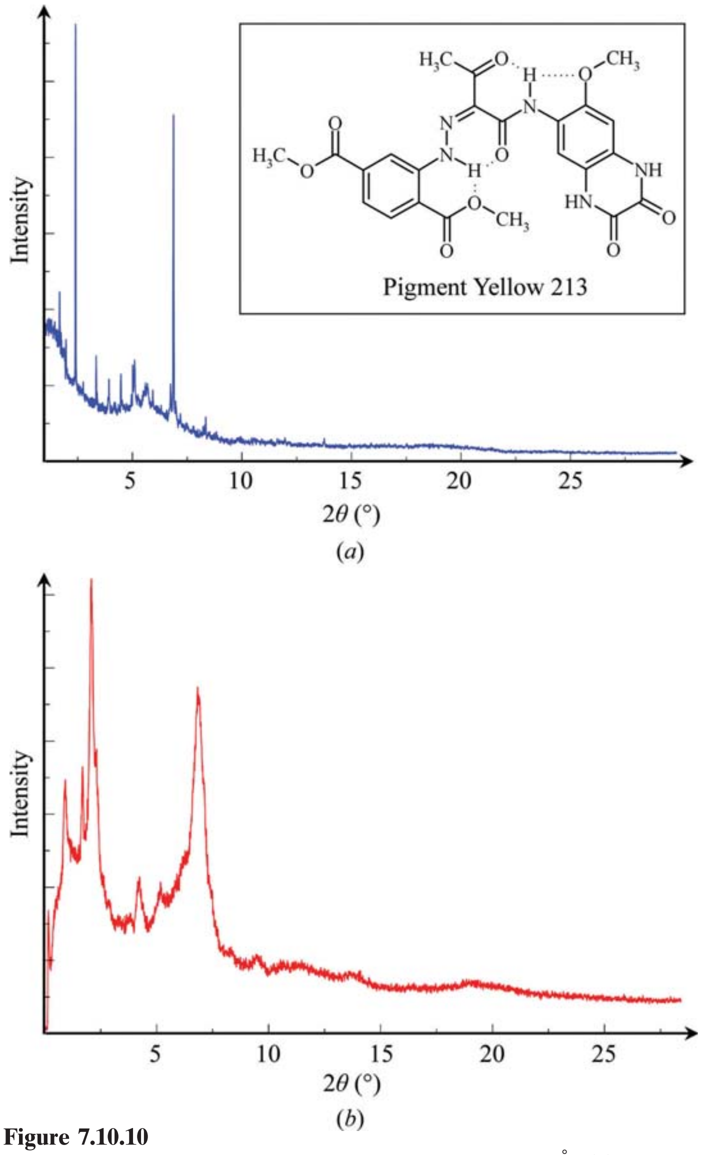

Figure 7.10.10
X-ray powder patterns of Pigment Yellow 213; λ = 0.40 Å. (*a*) α-phase, (*b*) β-phase.

(λ = 0.40 Å) over a large 2θ range. After background correction, normalization and Fourier transformation, the PDF curves were obtained (Fig. 7.10.12).

The PDF curve of the α-phase exhibits a regular sequence of maxima and minima with a periodicity of 3.3 Å. This regular feature is caused by the layer structure: atoms in neighbouring layers have distances of 3.3 Å. Interatomic distances of 3.3, 6.6, 9.9, 13.2, 16.5 Å *etc.* occur for many atom–atom pairs; this is reflected in the PDF. In other directions interatomic distances can adopt all values and do not lead to characteristic features in the PDF. At r values around 100 Å, the PDF curve still shows minima and maxima, which shows that the ordering length (domain size) in the stacking direction is much larger than 100 Å.

The PDF curve of the β-phase also shows this regular feature, as in the α-phase. Hence the molecules are also stacked (either in a layer structure or in a herringbone packing). The PDF curve of the β-phase vanishes at about 40 Å (4 nm); thus, the ordering length in the stacking direction is about 4 nm, which corresponds to stacks of 10–15 molecules only. This explains the absence of a sharp Bragg reflection at d = 3.3 Å in the X-ray powder pattern of the β-phase. From the width of the three low-angle reflections in the X-ray diffractogram the domain size in the lateral direction can be estimated as 100–200 Å, corresponding to the length and width of about ten molecules.

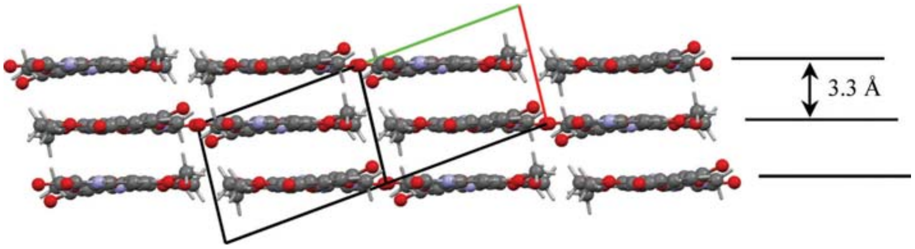

Figure 7.10.11
Crystal structure of the α-phase of Pigment Yellow 213 (Schmidt, Brühne *et al.*, 2009).

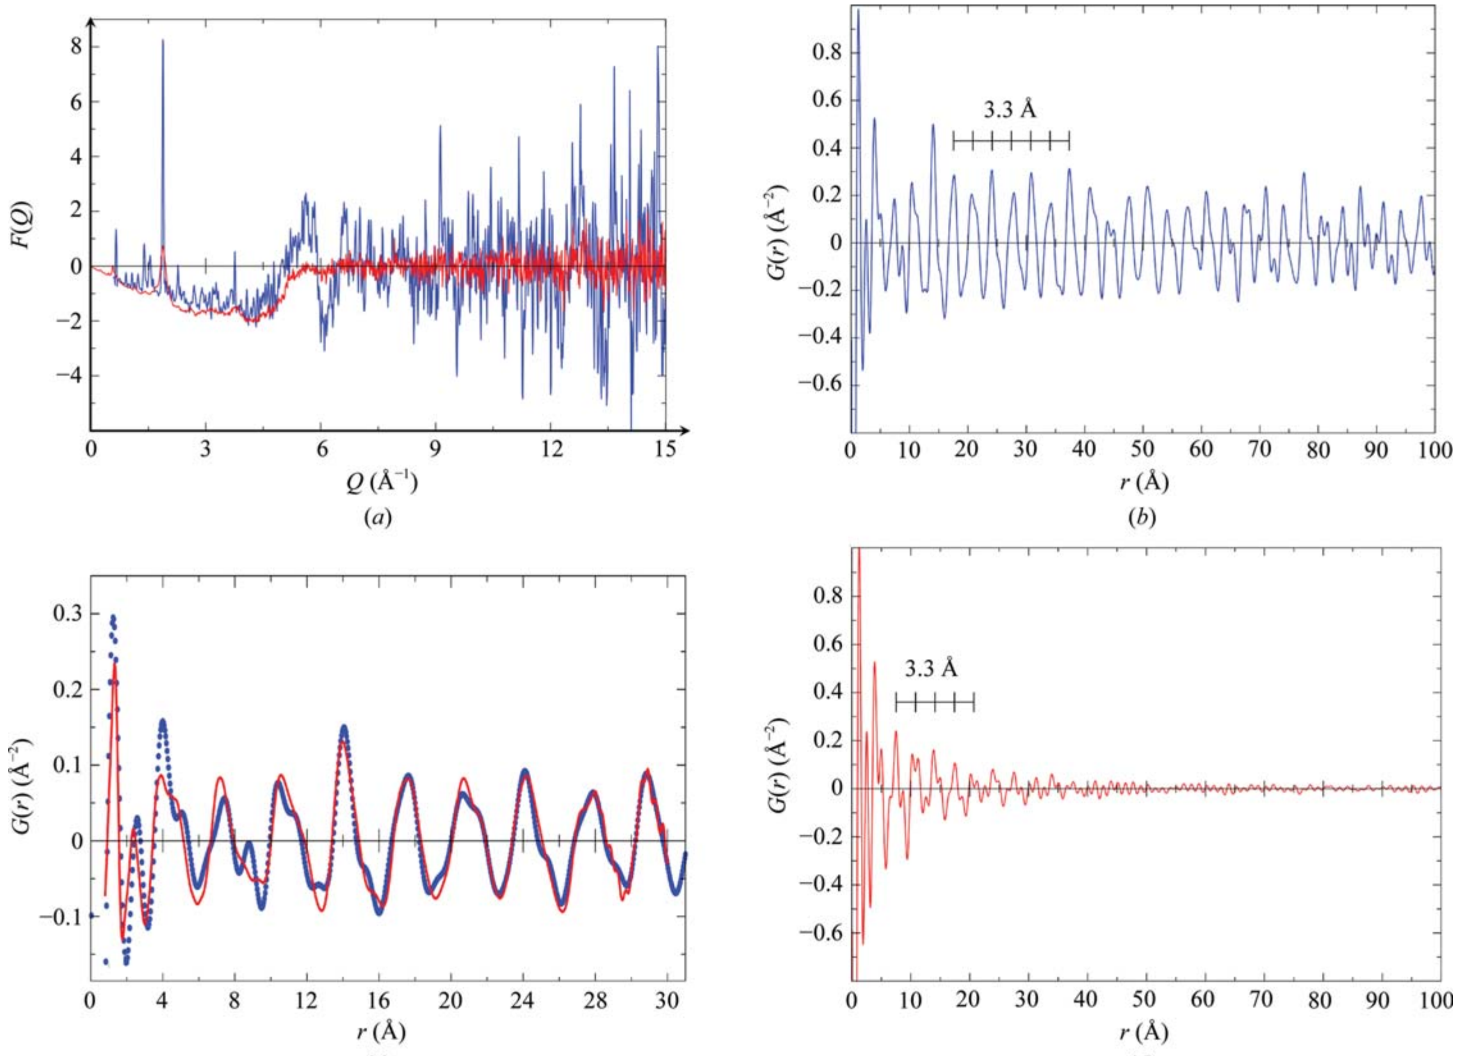

Figure 7.10.12

Pair-distribution function analyses of Pigment Yellow 213. (*a*) Synchrotron powder patterns after normalization with the α-phase in blue and the β-phase in red. $\lambda = 0.40$ Å, $Q_{\max} = 15$ Å^{-1}. (*b*) The PDF curve of the α-phase. (*c*) Comparison of the experimental PDF curve of the α-phase (blue) and the PDF simulated from the crystal-structure data for the α-phase (red). The peak width was fitted with two parameters (δ, φ); the lattice parameters and atomic coordinates were not modified. (*d*) PDF curve of the β-phase.

This example shows that a powder pattern of an almost amorphous compound, which seemed to contain no information at all, still contains valuable information on the local structure, for example on the molecular arrangement, and the domain size in different spatial directions.

7.11. Powder diffraction in the petroleum and petrochemical industries

J. A. Kaduk

7.11.1. Introduction

The petroleum industry is generally divided into two parts: exploration and production ('upstream'), and refining. Intimately associated with the refining business is the petrochemical industry. Together, refining and petrochemicals are generally referred to as 'downstream' operations. Given the huge scale and economic importance of the industry, probably more X-ray powder-diffraction measurements are made in it than in any other industry. Relatively few are published, given the highly proprietary nature of the information obtained. A comprehensive review of the applications of powder diffraction in the petroleum industry is impossible within any reasonable length, but a selection of recent representative examples are presented to illustrate the breadth of applications of powder diffraction in both the upstream and downstream sectors.

7.11.2. Exploration and production

The largest number of samples for X-ray diffraction (XRD) are analysed in support of exploration activities. Characterization of a single oil or gas well can easily involve hundreds of samples. Most of the analyses are considered routine, as they involve qualitative and quantitative phase identification. The analyses are not simple, however, because of the complex assemblies of minerals that are present in many rocks. The techniques and best practices described in other chapters of this volume should enable the analyst to carry out most such rock analyses. A strategy that is sometimes followed is to use a 'phase filter' (Morton *et al.*, 2001). This involves including in the input file of the Rietveld program all of the phases that might possibly be encountered in a particular set of samples. This could include 20–30 phases. The initial refinements involve only the scale factors of each phase. Those that refine to zero (or negative values) are fixed at zero, and subsequent refinements are used to examine the microstructural characteristics and concentrations of the phases that are actually present.

Generally, the powder-diffraction measurements in a geological study are a (small) part of a multi-technique investigation. A typical recent example is given in Glikson *et al.* (2010). Many samples of cuttings from drilling the well were examined to establish the stratigraphy and mineralogy of the formations. Most of the analysis was performed using electron microscopy, with powder diffraction serving to confirm mineral identifications and quantify their concentrations.

7.11.2.1. *Rock properties*

Characterizing the phases that are present is important not only in itself, but also for understanding the properties of the rock. Jiu *et al.* (2013) found that lacustrine shale reservoirs in the Zhanhua Depression consisted mainly of detrital minerals, carbonates and clay minerals. The detrital minerals included quartz and several feldspars. (Feldspar identification and quantification can be a real challenge, given the extensive peak overlap of these phases.) The carbonate minerals included calcite, dolomite and a small concentration of siderite. The clay minerals included a mixed illite/smectite, illite, kaolinite and chlorite. Quartz, feldspars and carbonates are considered to be the main brittle minerals in shale reservoirs (Hill & Nelson, 2000), so the bulk mineral analysis is important for predicting the fracture properties of the rocks in contemporary fracking operations.

The mudstones of the Belle Fourche and Second White Specks formations change with depth (Furmann *et al.*, 2014). These shales are composed of clay minerals (illite, kaolinite and chlorite), quartz, feldspar (albite), carbonates (calcite, dolomite and ankerite) and pyrite. The compositions are conveniently visualized in a ternary diagram of quartz + albite, carbonates and clays. The mineralogy correlates well with a 'ternary diagram' of macropores, mesopores and micropores. Mudstones containing >65 wt% quartz + feldspar are commonly more permeable than rocks with lower concentrations of these phases. Based on the quantified mineralogy, the brittleness of the rocks was calculated according to Jarvie *et al.* (2007) and Wang & Gale (2009).

7.11.2.2. *Clay mineralogy and the Reynolds Cup*

The most important part of a mineralogical analysis often lies in the clay minerals, for their identification and quantification can be used to assess the thermal history of the reservoir, and thus the nature of the petroleum which may be found in it. Analysis of the clay minerals using diffraction techniques is, however, the most difficult part of the analysis, because these minerals are often not ordered in three dimensions, and their layers are prone to intergrow. While it is often possible to 'force' crystalline models on these phases and obtain answers which are 'good enough' from a Rietveld refinement, such crystalline models are more of an approximation than they are for most phases, and special techniques are often required. These can include the PONCKS techniques described in Chapter 3.9, but special-purpose (non-Rietveld) software can be required. Such techniques will be facilitated by the inclusion of raw data patterns in the Powder Diffraction File (PDF; Chapter 3.7).

A renaissance in methods for clay mineral analysis dates from an inter-laboratory comparison (Ottner *et al.*, 2000). Since 2002, the Clay Minerals Society has sponsored seven Reynolds Cup challenges for mineral analysis (http://www.clays.org/Reynolds.html). The details of the methods used by the top finishers in the Third Reynolds Cup are documented in Omotoso *et al.* (2006).

Obtaining accurate phase identifications and quantifications required more effort than might be considered typical. Examination of the samples using optical and electron (with energy-dispersive spectroscopy) microscopes assisted in phase identification. Size fractionation (less and greater than 2, 6 or 20 µm, depending on the participant) helped to identify the clay minerals. Key to identifying the clay minerals were the usual treatments (air drying, magnesium and/or potassium exchange, ethylene-glycol intercalation, formamide intercalation and heating) and measurements of oriented specimens on glass slides. Additional treatments, such as washing with water, acid (to remove carbonates) and ethylenediaminetetraacetic acid (EDTA), can simplify analysis of the insoluble fractions.

Copyright © 2019 International Union of Crystallography

Patterns for quantitative analysis were generally collected from micronized specimens containing an internal standard. Most analyses were carried out by the Rietveld method. Key to the highest accuracy was comparison of the analysis calculated from the phase compositions and concentrations with that obtained by bulk chemical analysis. It was also important to use optimized structural models for the phases that were actually present, rather than 'random' models from a database.

7.11.2.3. *Gas hydrates*

Clathrate hydrates (or gas hydrates) are nonstoichiometric crystalline compounds formed by physical interactions (van der Waals forces) between a framework of hydrogen-bonded water molecules and guest molecules (Sloan & Koh, 2008; Atwood *et al.*, 1984). Three common structures designated I, II and H are known, mainly depending on the size of the molecular guest species. There is growing interest in gas hydrates for their potential application as a source of natural gas (Ji *et al.*, 2001), for deep-ocean CO_2 sequestration (Teng *et al.*, 1997) and for the recovery/separation of greenhouse gases from flue gas (Kang & Lee, 2000) because they can hold a large amount of gas in a small volume of solid hydrate phase.

The unexpected formation of gas hydrates during the production and transportation of natural gas is a severe problem (Kelland, 2006). Hydrate formation may block pipelines, creating a safety hazard (Ostergaard *et al.*, 2005). Accordingly, extensive work has been performed on inhibitors of gas-hydrate formation. Park *et al.* (2013) found that morpholine was a good inhibitor of methane hydrate formation and used powder diffraction to identify and quantify gas-hydrate phases.

7.11.2.4. *Corrosion deposits*

Corrosion-related failure of equipment which produces or transports hydrocarbon fuels can be catastrophic and newsworthy. A common task in an XRD laboratory is to characterize corrosion deposits (either pre-failure or post-failure) in an attempt to deduce the conditions that led to the corrosion and to prevent future failures.

The corrosion scale on a failed low-alloy Qinhuangdao–Shenyang natural gas pipeline consisted mainly of $FeCO_3$ (Shi *et al.*, 2014). Iron and Fe_3C from the uncorroded steel were also detected. No iron oxides were observed, as might be expected from the oxygen-free environment. The natural gas contained 2.27 mol% CO_2 and 2.58 mol% H_2O. Dry CO_2 cannot corrode steel; the presence of water is required. The siderite scale indicated that the corrosion was electrochemical in nature. The $FeCO_3$ was porous, so ion transport and pitting were facilitated once the siderite began to form.

Many well and pipeline deposits consist of mixtures of iron sulfides. Quantitative phase analysis, in conjunction with iron–sulfur phase diagrams, can provide detailed information on the conditions that led to the formation of the scale. The presence of the FeS polymorph mackinawite almost always indicates bacterial involvement in the corrosion.

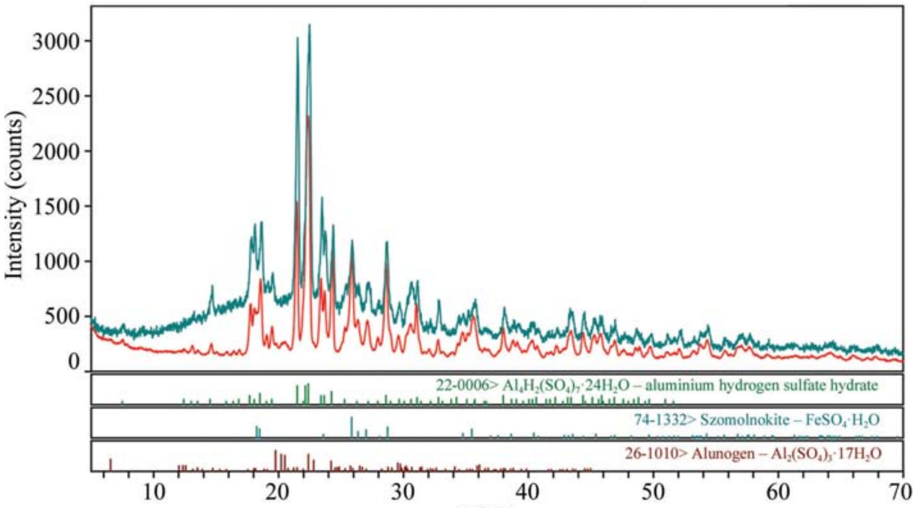

Figure 7.11.1
X-ray powder patterns of an alkylation-unit pump-seal deposit, both as received (green) and after removing the amorphous organic fraction by washing with acetone (red).

7.11.3. Refining and petrochemicals

7.11.3.1. *Corrosion deposits*

New phases are encountered remarkably often in support of the petroleum and petrochemical industries. These present both a problem (because their structures are not known and thus are harder to include in a Rietveld refinement) and also an opportunity to solve interesting new structures. The commercial value is generally not in the new structures themselves, but in understanding how/why these compounds came to be present in the sample.

7.11.3.1.1. $[Al(H_2O)_6][Al(H_2O)_5(SO_4)](H_3O)_2(SO_4)_5$

A black tar was recovered from a pump seal at a refinery alkylation unit. The process engineers were concerned that sulfuric acid had leaked into this pump, which had an aluminium housing. The powder pattern (Fig. 7.11.1) indicated that this tar contained the crystalline phases $Al_4H_2(SO_4)_7{\cdot}24H_2O$ (PDF entry 00-022-0006), szomolnokite, $FeSO_4{\cdot}H_2O$ (PDF entry 01-074-1332), and alunogen, $Al_2(SO_4)_3{\cdot}17H_2O$ (PDF entry 00-026-1010). The amorphous hydrocarbon present in the tar could be removed by washing with acetone. (Knowing how to deconstruct and separate samples is a useful skill.) At the time, the crystal structure of $Al_4H_2(SO_4)_7{\cdot}24H_2O$ had not been determined, so the structure had to be derived before the Rietveld quantitative analysis could be carried out.

The structure was solved by analogy using the formula type ANX in the Inorganic Crystal Structure Database (http://icsd.fiz-karlsruhe.de; Bergerhoff & Brown, 1987; Belsky *et al.*, 2002; Hellenbrandt, 2004). By the conventions of the ICSD, $Al_4H_2(SO_4)_7{\cdot}24H_2O$ has the formula type ANX = A4B7X52. At the time of this work, the ICSD contained only one entry with this formula type, that of $Cr_4H_2(SO_4)_7{\cdot}24H_2O$. Although the pattern of this chromium compound does not appear to match that of the aluminium compound very well (Fig. 7.11.2), the two compounds are in fact isostructural. Substituting Al for Cr in the reported structure (Gustafsson *et al.*, 1980) led to an excellent Rietveld refinement. Details of the refinement can be found in Kaduk (2002*a*). After the problem had been solved, a single-crystal structure of $Al_4H_2(SO_4)_7{\cdot}24H_2O$ was reported (Fischer *et al.*, 1996).

From the refined scale factors, the crystalline portion of the deposit contained 70 wt% $Al_4H_2(SO_4)_7{\cdot}24H_2O$, 22 wt%

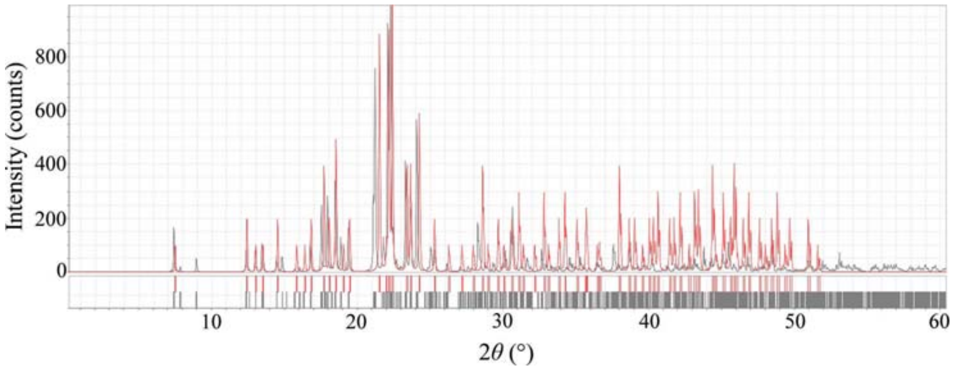

Figure 7.11.2
Comparison of the powder patterns of the isostructural compounds $Al_4H_2(SO_4)_7 \cdot 24H_2O$ (red) and ‘$(H_3O)_2Cr_4(SO_4)_7(H_2O)_{22}$’ (grey) = $Cr_4H_2(SO_4)_7 \cdot 24H_2O$.

$FeSO_4 \cdot H_2O$ and 8 wt% $Al_2(SO_4)_3 \cdot 17H_2O$. The Fe:S ratio calculated from these concentrations agreed well with the value of 0.27 determined by bulk chemical analysis. The Al:Fe and Al:S ratios of 2.02 and 0.45 were lower than the bulk values of 2.76 and 0.75, respectively. The conclusion was that the amorphous fraction of the tar contained Al. By combining the bulk chemical analysis with the Rietveld results, the true concentrations of these three phases in the whole deposit were 23, 7 and 3 wt%, respectively.

The most complete investigation of the $Al_2(SO_4)_3$–H_2SO_4–H_2O system (Taylor & Bassett, 1952) indicates that $Al_4H_2(SO_4)_7 \cdot 24H_2O$ is formed around 323–333 K at H_2SO_4:$Al_2(SO_4)_3$ ratios from 2.4 to 14.5, or acid-rich conditions. It was obtained by the slow transformation of $Al_2(SO_4)_3 \cdot 16H_2O$ or $Al_2H_2(SO_4)_4 \cdot 12H_2O$ and is metastable with respect to $Al_2(SO_4)_3 \cdot 14H_2O$. Apparently, sulfuric acid had leaked into the pump and reacted with both the aluminium housing and steel pump parts. The fact that the major phase is metastable with respect to other hydrated aluminium sulfates suggested that the corrosion was current and not a historical event. Accordingly, the recommendation was made to shut this unit down to repair the pump, rather than wait a few months for the scheduled shutdown and risk a catastrophic failure.

7.11.3.1.2. *$(NH_4)Fe(CO_3)(OH)_2$*

After the liquid-ammonia supply to a chemical plant was changed, deposits began to form in a liquid-ammonia heat exchanger. Such deposits reduce the efficiency of the exchanger, so identifying their nature (and thus their cause) had a significant impact on process economics. These deposits contained mixtures of phases, including PDF entry 00-022-0052, ‘$(NH_4)_2Fe(OH)_4(CO_3)_2(H_2O)$’ (Dvořák & Feitknecht, 1969). This compound had only been reported in one other reference (Erdös & Altorfer, 1976) as a corrosion product of carbon steel in aqueous solutions of ammonia and carbonic acid. Before the Rietveld quantitative analysis could be carried out, it was necessary to determine the structure of this compound.

The compound was prepared nearly phase-pure by the method of Dvořák & Feitknecht (1969). The powder pattern could be indexed in a *C*-centred orthorhombic unit cell with $a = 6.6154\ (6)$, $b = 12.0639\ (10)$, $c = 6.0263\ (5)$ Å. Default reduced-cell searches yielded no hits. Both from the process chemistry and the PDF entry, we could be reasonably sure that the compound contained carbon, hydrogen, nitrogen and oxygen. A search of the ICSD for compounds containing these elements and having *C*-centred orthorhombic unit cells yielded 25 hits, most of which could be discarded as they were cyanide complexes. Among the hits was ‘NH_4-dawsonite’, $(NH_4)Al(CO_3)(OH)_2$ (Iga & Kato, 1978), which had also been reported as a corrosion product by Erdös & Altorfer (1976). (Dawsonite is the sodium analogue.) The bulk chemical analysis reported by Dvořák & Feitknecht (1969) accounted for only 86.5% of the product, suggesting that their formulation was incorrect.

$(NH_4)Al(CO_3)(OH)_2$ proved to be a suitable starting model for $(NH_4)Fe(CO_3)(OH)_2$, the correct formulation of this phase (Fig. 7.11.3). Details of the refinement are given in Kaduk (2002*a*). Synthesis of $(NH_4)Fe(CO_3)(OH)_2$ requires CO_2 and H_2O, neither of which should have been present in the liquid-ammonia feed system. After careful examination of the system for leaks (and finding none), we concluded that these deposits were a startup problem (resulting from an incompletely cleaned pipeline) and not a failure of the system. After the initial formation the deposits did not return, confirming the conclusion.

7.11.3.1.3. *$(NH_4)Fe_2S_3$*

A deposit isolated from a refinery isomerization-unit pump screen contained several normal sulfide and oxide corrosion phases (Fig. 7.11.4), but the best match to the pattern of the major phase was rasvumite, KFe_2S_3. The presence of rasvumite would be very surprising, as there should be no potassium in a refinery stream, and none was detected by bulk chemical analysis. The jar containing the deposit smelled strongly of ammonia when it was opened. Ammonium and potassium ions are similar in size, and often form isostructural compounds. The infrared spectrum of the deposit was dominated by bands from NH_4^+ cations. Accordingly, the rasvumite structure was used as the initial model for the major phase, $(NH_4)Fe_2S_3$. The Rietveld refinement (Fig. 7.11.5)

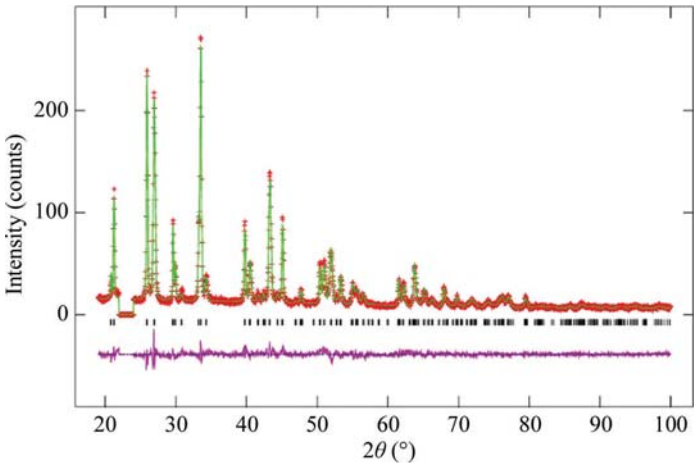

Figure 7.11.3
Rietveld refinement of $(NH_4)Fe(CO_3)(OH)_2$ based on the ‘NH_4-dawsonite’ model.

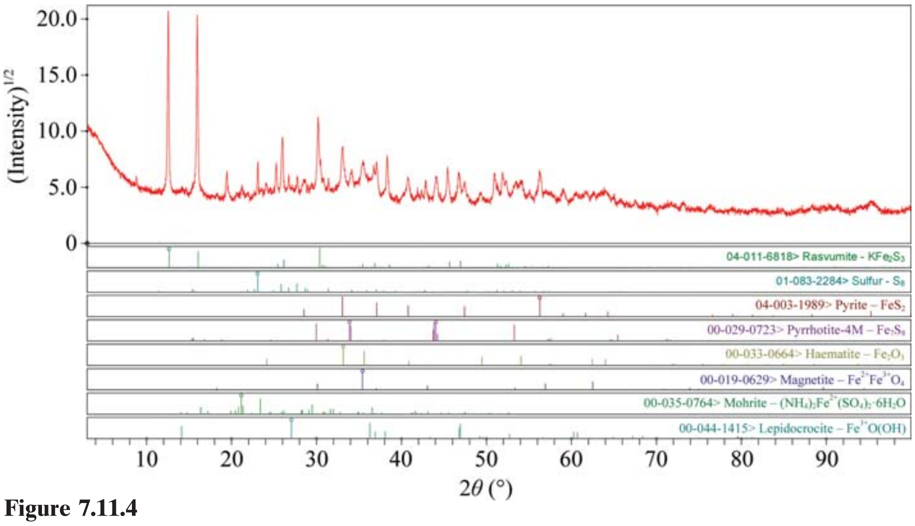

Figure 7.11.4
Powder pattern of a refinery isomerization-unit pump-screen deposit. The best match to the major phase was the chemically unreasonable KFe_2S_3.

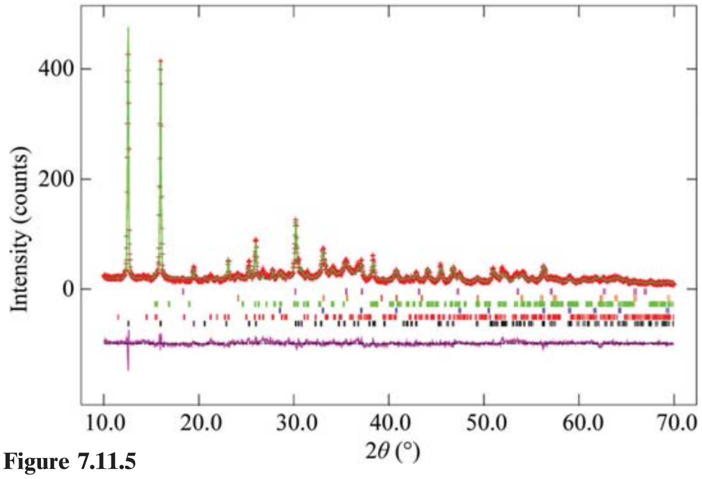

Figure 7.11.5
Rietveld refinement of the refinery isomerization-unit pump-screen deposit.

yielded the composition as 34.8 (3) wt% $(NH_4)Fe_2S_3$, 8.1 (3)% S_8, 10.4 (2)% pyrite (FeS_2), 5.0 (2)% pyrrhotite (Fe_7S_8), 30.6 (4)% magnetite (Fe_3O_4) and 11.0 (2)% haematite (Fe_2O_3). The deposit was not an unreasonable refinery corrosion deposit. The powder pattern and crystal structure of $(NH_4)Fe_2S_3$ are now included in the PDF as entry 00-055-0533.

7.11.3.2. *Catalysts*

Some of the preceding examples come from the 'upstream' (exploration and production) side of the petroleum industry. An important part of the work of most XRD laboratories in this industry is characterizing catalysts from the 'downstream' side (refining and chemicals). Such catalysts are often highly proprietary, but a few examples can be provided. Other examples are given in Medrud (2000) and Teller (2000).

7.11.3.2.1. *Quantitative analysis of zeolite catalysts*

ASTM method D5758-01 concerns the determination of the crystallinity of molecular sieves with the MFI framework type. It involves determining the integrated area of the 501/051/151/303/133 peak cluster (Fig. 7.11.6) and comparing it with the area from a reference sample. Similar methods exist for the FAU (D3906-03) and LTA (D5357-03) framework types. Although most zeolite quantitative analysis is currently performed using the Rietveld method, such peak-based methods have a role when high-volume and/or fast-turnaround analyses are necessary.

Zeolites and supported zeolite catalysts present special challenges for quantitative analysis. Everything about the procedures must be carefully controlled to achieve the highest accuracy and precision. The water content (and thus the unit-cell formula) varies with relative humidity, which must therefore be controlled. The equilibration time is often several hours, and often an overnight equilibration in a controlled-humidity chamber is required. The equilibration profile varies with framework type and composition, and must be determined experimentally for the system of concern.

Ion exchange (especially with high-*Z* metal cations) can change the absorption coefficient of the sample significantly. Since such methods rely on an external standard, it is important to calculate whether identical specimen volumes are illuminated in the exchanged specimen and the (generally metal-free) reference zeolite. It is possible to follow the ASTM method rigorously and obtain the wrong answer!

Any method should be qualified by making known mixtures of the reference zeolite and an appropriate support or amorphous phase. Blending of an MFI reference with γ-alumina can lead to microabsorption effects. These can be eliminated by micronizing the blend. Since micronizing requires a milling liquid, additional steps of removing the adsorbed liquid and re-equilibration are required. Certain large-crystallite Al-MFIs (ZSM-5) can be prone to preferred orientation and microabsorption, which can also be eliminated by micronizing and subsequent re-equilibration. Micronizing can change the amount and functional form of water absorption, and the supports (and internal standards!) can have a significant absorption capacity.

It is not rare for specimen preparation to change the as-received sample. The symmetry of the MFI can change from orthorhombic to monoclinic on grinding. Other phases can change polymorphs or be destroyed by grinding. The stability of each system of interest must be determined experimentally.

Even the data-processing method must be carefully controlled. The integrated areas are generally determined by profile fitting. We have found that we obtained more accurate and more precise

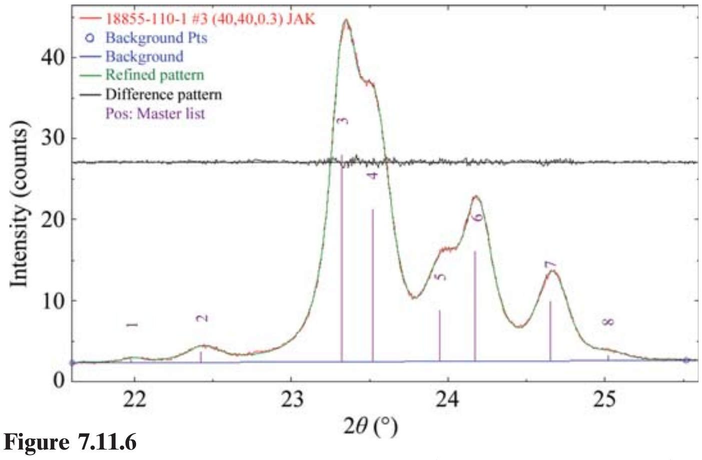

Figure 7.11.6
Profile fit of the 501/051/151/303/133 peaks (the five strongest peaks) to determine their integrated areas in ASTM method D5758-01 for the determination of the crystallinity of MFI molecular sieves.

integrated areas of the five strong peaks by including the three small peripheral peaks in the profile fitting. The shape of the profile can change the integrated areas. Even the background (which is generally assumed to be linear in this small region) can affect the resulting peak areas. Using 22–25° and 22.5–25° as background points can result in different integrated areas and thus quantitative analyses. Such data-processing issues are less of a problem when whole patterns are used in a Rietveld analysis, but background functions and structural models must be optimized and controlled.

Despite all of these cautions, with careful control of all steps of the analysis absolute accuracies of <0.2 wt% can be achieved for supported zeolite catalysts.

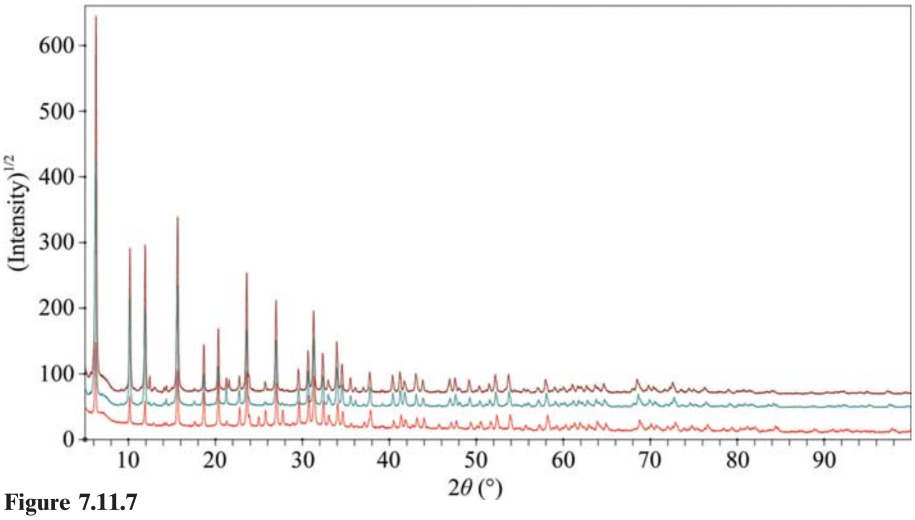

Figure 7.11.7
Patterns of Na-FAU measured under ambient conditions (red) and dehydrated both at 623 K (brown) and 298 K (green).

7.11.3.2.2. *Extraframework sites in Na-FAU*

Zeolites are crystalline aluminosilicates composed of corner-sharing tetrahedra joined into three-dimensional frameworks having pores of molecular dimensions. They are a subset of the larger class of molecular sieves. A pure silica framework is neutral. The presence of aluminium in the framework results in a negative framework charge, which is balanced by cations. These cations are relatively mobile and can be replaced using standard ion-exchange techniques. Faujasite (International Zeolite Association structure type FAU; Meier *et al.*, 1996) crystallizes in the cubic space group $Fd\bar{3}m$, with a lattice constant ranging from about 24.2 to 25.1 Å, depending on the framework aluminium concentration, cations and the state of hydration. There are 192 tetrahedral sites per unit cell. This zeolite is most conveniently visualized as being formed from 24-tetrahedra cuboctahedral units (sodalite cages) joined through hexagonal prisms (also known as double 6-rings). The structure can be viewed as the diamond structure, with the sodalite cages playing the role of C atoms and the double 6-rings the role of C—C bonds.

The pore structure is characterized by supercages approximately 12 Å in diameter with cavities which are linked through 12-ring windows of about 8 Å in diameter. These cages and pores permit access to quite large molecules, making this structure useful in catalytic applications. It is not much of an exaggeration to say that each drop of gasoline passes through this zeolite at least once.

The most commonly encountered faujasites are zeolite X (higher Al) and zeolite Y (lower Al). Zeolite Y is the most important catalytic zeolite, and is generally synthesized in the sodium form. Most of the catalysis of interest is acid catalysis, which requires replacing the sodium cations by protons, converting the sieve into the hydrogen form. This cannot be performed by direct ion exchange, since most H-faujasites are not acid stable. An indirect strategy is therefore used. Ammonium exchange is carried out, followed by calcination to decompose the NH_4^+ cations into ammonia and protons. In this way, highly crystalline H-FAU can be prepared. In some catalytic applications, it is desirable to incorporate metal cations into the sieve to modify the number and nature of the acid sites and to affect the diffusion of reactants and products. A detailed *in situ* study of extraframework species in FAU can be found in Kaduk (2005) (data files are available from the author on request).

The crystal structures of the hydrated Na-FAU LZ-Y52 starting material and the dehydrated material have been determined at both 623 and 298 K using *in situ* measurements on a laboratory diffractometer.

A sample of LZ-Y52 was packed into a 0.4 mm deep corundum holder. The X-ray powder pattern was first measured under ambient conditions on a PANalytical X'Pert Pro diffractometer equipped with a PIXcel position-sensitive detector and an Anton Paar HTK1200N furnace. The sample was heated to 623 K in vacuum (~3.2 × 10^{-5} mbar; 1 mbar = 100 Pa) and the pattern was re-measured *in situ*. The pattern was also measured after cooling to 298 K in vacuum. The faujasite crystal structure was refined by the Rietveld method using *GSAS* (Larson & Von Dreele, 2000).

By using the correlation of Fichtner-Schmittler *et al.* (1984) between the cubic lattice parameter and the framework Al concentration and the weight loss on dehydration, the formula of LZ-Y52 was the well known $Na_{56}Al_{56}Si_{136}O_{384}(H_2O)_{198}$. The powder pattern of the hydrated material differs from those of the dehydrated forms in subtle but important ways (Fig. 7.11.7), reflecting differences in the crystal structures.

The refinement of the structure of the hydrated zeolite is not particularly good (Fig. 7.11.8 and Table 7.11.1). Only some of the sodium cations can be located (as is typical for hydrated zeolites); the difference Fourier map is flat to ±0.7 e Å^{-3}. Site II′ is

probably occupied by water molecules rather than sodium cations. The remaining sodium ions are disordered in the almost-liquid water that fills the large pores of this zeolite. Local ordering on the scale of a few unit cells results in distortion of the peak intensities. Attempts were made to use the solvent-flattening capability of *GSAS* (which is usually used for refining protein structures) to model this water, but the coefficients refined to values that were insignificantly different from zero and the refinements became unstable. Hydrated zeolites are difficult to describe using a purely crystalline model.

Better refinements were obtained for the dehydrated zeolite at both 298 and 623 K (Figs. 7.11.9 and 7.11.10) because there are no disordered water molecules. Almost all of the sodium cations could be located (49 and 52 sodium cations per cell at 298 and 623 K, respectively). They occupy sites I (double 6-rings), I′ (sodalite cage) and II (supercage) (Fig. 7.11.11), but the site occupancies are different at the two temperatures. In dehydrated Na-FAU site I is almost completely occupied by sodium at room temperature. At 623 K about half of these sodium cations move to site I′; the total number of cations in these two sites is nearly constant. Occupation of site I precludes occupation of two sites I′ (the sites are too close together for simultaneous occupancy), so the distribution of the cations reflects a subtle shift in the relative energies of the two sites at the two temperatures. The occupation of site II is nearly constant at the two temperatures. These results are in excellent agreement with other structure determinations of dehydrated Na-FAU.

Compared with the dehydrated form, Na I′ in hydrated LZ-Y52 is ~0.4 Å farther from the framework, indicating

coordination to water molecules (Fig. 7.11.12). These water molecules occupy site II′, which is empty in the dehydrated zeolite. Site II is empty in the hydrated zeolite, showing that the remaining sodium cations are coordinated to water molecules ‘in solution’ in the large pores.

Different cations occupy different sites at elevated (close to reaction) temperature and move differently when the sample is returned to ambient conditions (Kaduk, 2005). In a CaNa-FAU containing $Ca_{20}Na_{10}$ in the unit cell, hydrated calcium ions are approximately equally distributed over sites I′, II′ and II under ambient conditions. There is also a small population of hydrated calcium cations at site V. At 573 K there are large calcium populations at site I, and sites I′ and II are populated by a mixture of calcium and sodium. All of the cations were closer to the framework O atoms than under ambient conditions. On cooling to ambient conditions (and rehydrating) the cations move to positions that are not greatly different from their initial positions. A second calcium exchange to the composition $Ca_{27}Na_4$ led to very different cation locations at 573 K. Site I is vacant, but site I′ is half-occupied by calcium. Cation–cation repulsions preclude simultaneous occupation of sites I and I′. The remaining calcium cations occupy site II, and the sodium cations are displaced to the relatively unfavourable site II′.

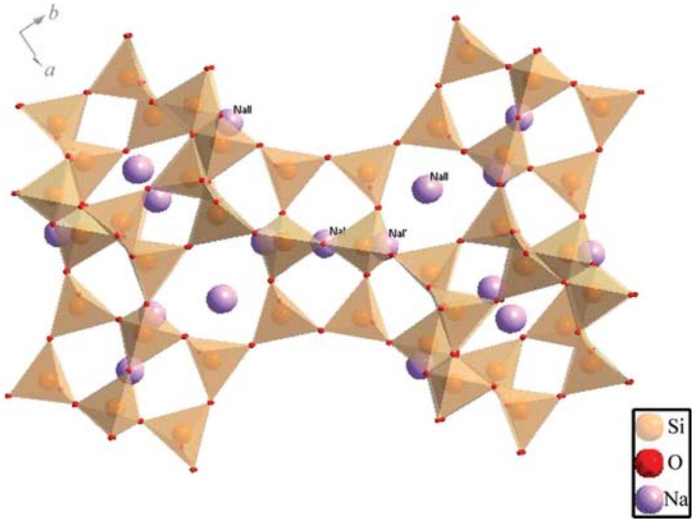

Figure 7.11.11
Positions of the sodium cations in dehydrated Na-FAU at 298 K.

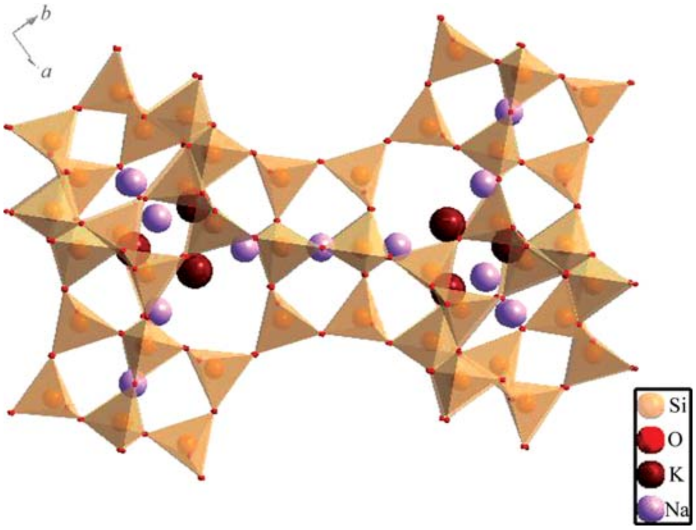

Figure 7.11.12
Positions of the sodium cations in dehydrated Na-FAU at 573 K. The sodium at site II′ is designated ‘K’ to distinguish it from the other sodium sites I and I′.

Barium cations occupy sites I′ and II, as well as an additional site in the supercages. In $La_{15}Na_{13}$ most of the lanthanum cations occupy site V, far away from the framework O atoms, and small lanthanum populations occupy sites I′, II and II′; the sodium cations also occupy site II′. At 573 K the great majority of the lanthanum cations occupy site I′, and the sodium cations are displaced to site II′. Unlike the calcium-exchanged FAU, the lanthanum cations tend to remain at their high-temperature positions on cooling and rehydration.

A zinc-edge resonant-scattering study (both under ambient conditions and *in situ* at 573 K) permitted determination of the zinc and sodium site occupancies in $Na_{13}Zn_{19}$-FAU. In the hydrated sample at ambient conditions the Zn cation occupy sites II′ and II, with the sodium cations at site I′. Electron density at the centre of the sodalite cage (site U) represents an O atom coordinated to the zinc. At 573 K the zinc cations move to sites I′ and II′, and the sodium cations are displaced to site II in the supercage.

Each cation moved differently between ambient and catalytic temperatures. To develop a valid structure–activity correlation, the correct structure (measured *in situ*) must be used.

7.11.3.2.3. *Xenon in Na-FAU*

^{129}Xe NMR is often used to study the diffusion and porosity of zeolites. An Xe atom is almost the same size as a methane molecule. To help understand the NMR results, and to provide some insight into how a methane molecule might interact with the FAU framework, a sample of commercial Na-FAU (LZ-Y52) was dehydrated carefully in a capillary attached to a vacuum line (Kaduk, 2002*b*). The sieve was cooled to room temperature and

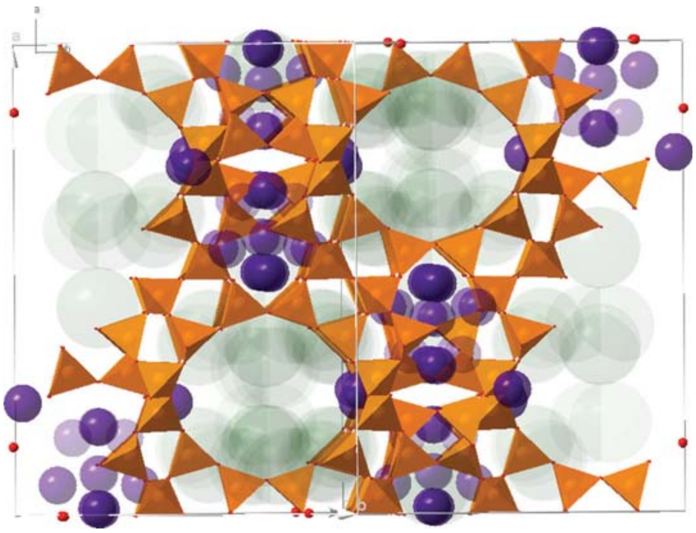

Figure 7.11.13
Extraframework xenon (and sodium) sites in Na-FAU at 20 K.

allowed to equilibrate with 1 atm xenon (1 atm = 101 325 Pa). The capillary was sealed and cooled to 20 K for measurement of the powder pattern. A total of 48 sodium cations per cell were located at sites I′, II′ and II (see Table V in Kaduk, 2005). Two additional extraframework sites, one near site III, a xenon van der Waals distance away from the framework O atoms, and another towards the centre of the supercage and a van der Waals distance away from site III, were found to be populated with Xe atoms (Table 7.11.2 and Fig. 7.11.13).

7.11.3.2.4. *CO_2 in Na-FAU*

The crystal structure of dehydrated Na-FAU with and without adsorbed CO_2 was determined at 4 K and at room temperature (RT) using neutron powder diffraction techniques (Wong-Ng *et al.*, 2013). Neutron diffraction data provided direct evidence that adsorption of CO_2 results in significant migration of the extraframework sodium cations in the zeolite structure. At 4 K, 45 of the apparent 76 CO_2 molecules per cell were located in two crystallographically independent sites bonding to the sodium cations (Na10) in the supercage site II. While the CO_2 molecule in the first site had a linear configuration, interacting with Na10 *via* one terminal O atom, the CO_2 molecule in the second site appeared to have a bent O—C—O configuration [148.3 (3)°], with both O atoms coordinating to two symmetry-related Na10 cations. Density-functional theory (DFT) total-energy calculations showed that the Na–CO_2 interaction slightly facilitates the bending motion of CO_2 by decreasing the energy cost for the 148.3 (3)° bond angle by ~0.2 eV per CO_2. However, this Na–CO_2 interaction is not sufficient to cause a 32° bond-angle distortion in CO_2 (an energy cost of ~0.66 eV per CO_2). Rotational disorder apparently plays a significant role here.

7.11.3.2.5. *Framework compositions*

One of the common zeolite analyses in an XRD laboratory is to calculate the framework composition from the refined lattice parameters. Correlations between the framework composition and the cell dimensions of carefully prepared samples are known for several common zeolite frameworks. Comparing the framework composition with the bulk chemical analysis easily yields estimates of the composition of amorphous and/or nonframework concentrations of heteroatoms.

Three different correlations between the cubic lattice parameter of faujasite and the framework aluminium content have been reported (Kerr, 1989; Breck & Flanigen, 1968; Kerr *et al.*, 1978; Dempsey *et al.*, 1969; Fichtner-Schmittler *et al.*, 1984; Sohn *et al.*, 1986):

$$\begin{aligned}\text{Breck–Flanigen}\quad & N_{\rm Al} = 115.2(a - 24.191),\\ \text{Kerr–Dempsey}\quad & N_{\rm Al} = 112.1(a - 24.222),\\ \text{Fichtner-Schmittler}\quad & N_{\rm Al} = 107.1(a - 24.338).\end{aligned}$$

The analyst has to work with the customer to determine which correlation is most appropriate for the systems being studied.

Correlations for both Al-MFI and B-MFI are reported in Meyers *et al.* (1985). Updated to current nomenclature, these correspond to $V = 5345 + 6.298$ Al per cell and $V = 5350 - 27.11$ B per cell (Fig. 7.11.14). Similar correlations have been reported for mordenite (Olsson & Rollmann, 1977).

7.11.3.2.6. *$(VO)_2P_2O_7$*

Vanadyl pyrophosphate is used commercially as a catalyst for the selective oxidation of butane to maleic anhydride. Rietveld analyses of a fresh catalyst and a catalyst that had been used for three years (Table 7.11.3) demonstrated that the fresh catalyst

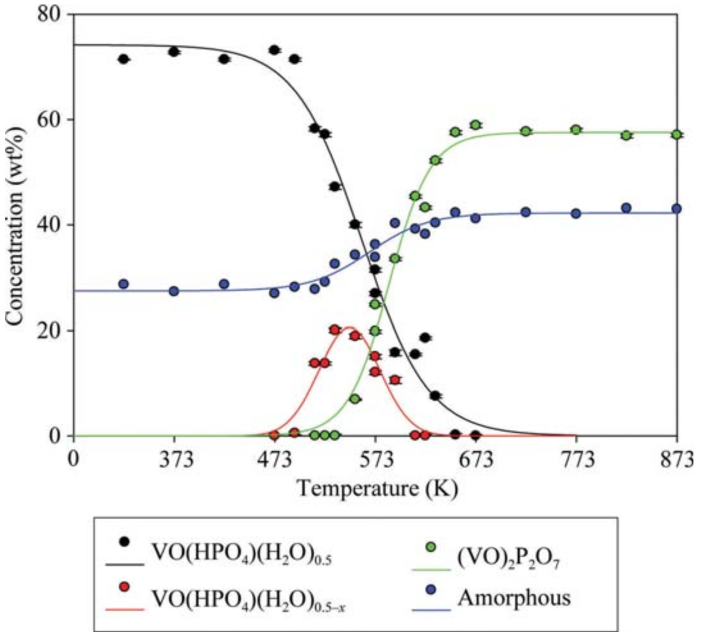

Figure 7.11.15

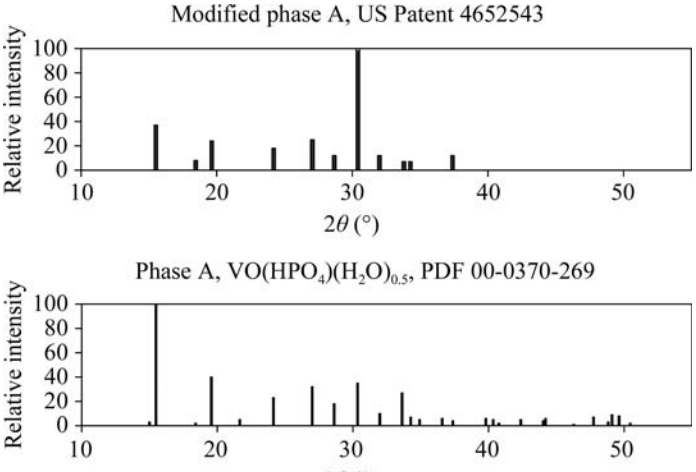

Figure 7.11.16
Powder patterns (as 2θ values and peak heights) of two morphologies of $VO(HPO_4)(H_2O)_{0.5}$. The differences in peak heights are the result of anisotropic size broadening.

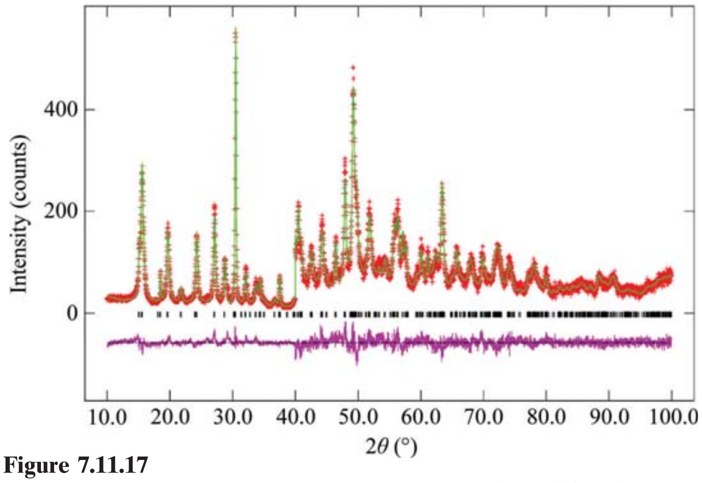

Figure 7.11.17
Rietveld refinement of ‘Modified Phase A’, $VO(HPO_4)(H_2O)_{0.5}$. The fixed published crystal structure model was used; anisotropic size-broadening profile coefficients account for the varying peak widths and peak heights compared with isotropic crystallites. The vertical scale has been magnified by a factor of 5× for angles greater than 40°.

contained small concentrations of two impurities: β-$VO(PO_3)_2$ and α-$VOPO_4$. The metaphosphate is a common impurity phase, while α-$VOPO_4$ indicated that the catalyst had been calcined under slightly oxidizing conditions. Its presence is detrimental, but both phases typically disappear in the first month of operation. Changes in the profile parameters indicated that the $(VO)_2P_2O_7$ had sintered only slightly in the three years of operation and that the anisotropic strain broadening had increased slightly.

Such catalysts are prepared by calcination of a $VO(HPO_4)(H_2O)_{0.5}$ precursor. *In situ* studies of the calcination confirmed that an intermediate phase occurred at intermediate temperatures (Fig. 7.11.15) and that the amount and nature of the amorphous phase changed during calcination.

Amoco Corporation obtained a patent for a ‘novel phosphorus–vanadium catalyst having a characteristic X-ray diffraction pattern’ (Edwards & Meyers, 1987). The composition of matter was defined by the stoichiometry $VO(HPO_4)(H_2O)_{0.5}$ and the characteristic powder pattern. The pattern exhibits some similarities in peak positions to that of $VO(HPO_4)(H_2O)_{0.5}$ (Fig. 7.11.16), but the relative peak heights of the two patterns are very different. A close examination of the pattern reveals that the peak broadening is highly anisotropic. A Rietveld refinement using a fixed structural model of $VO(HPO_4)(H_2O)_{0.5}$ (Leonowicz *et al.*, 1985) reproduced the observed pattern very well (Fig. 7.11.17) and demonstrated that there was no difference between the crystal structures of the two phases. There was thus no difference in the integrated intensities; anisotropic broadening caused the differences in peak heights. The refined profile coefficients indicated that the broadening was the result of size contributions, corresponding to plate-like grains averaging 170 × 840 × 840 Å. This morphology exposes more of the desirable {001} surface and thus explains the enhanced performance of the catalyst.

7.11.3.2.7. *Vent-gas oxidation catalyst*

A vent-gas oxidation catalyst in a chemical plant consisted of an array of cordierite monolith bricks. These monoliths were coated with a stabilized cubic zirconia wash coat and impregnated with platinum (Fig. 7.11.18 and Table 7.11.4). While no crystalline platinum was detected in the fresh catalyst, it had sintered significantly during use. The cubic zirconia also sintered, while the cordierite monolith was essentially unchanged. If the zirconia particles are spherical, their average diameter can be estimated: diameter = 6/(density × BET area) (where BET = Brunauer–

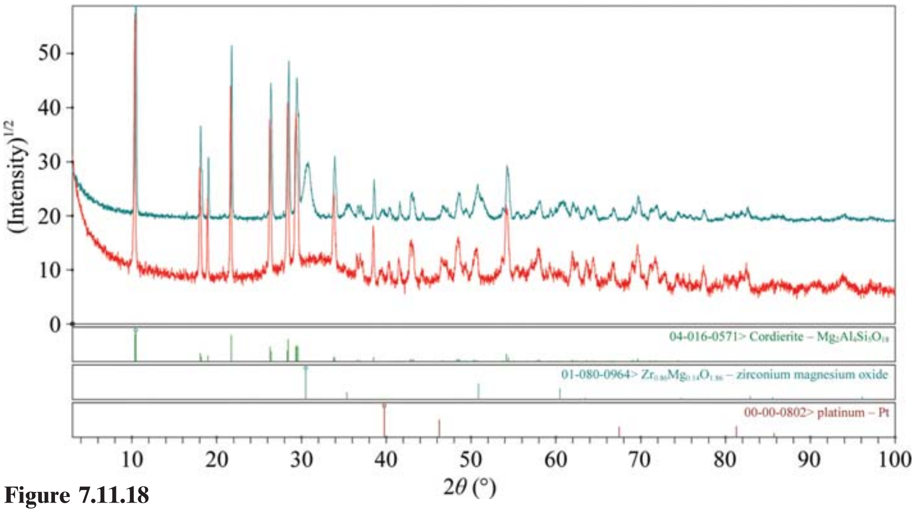

Figure 7.11.18
Powder patterns of a fresh (red) and used (green) vent-gas oxidation catalyst.

Emmett–Teller). These estimated diameters track the crystallite sizes calculated from the line broadening well.

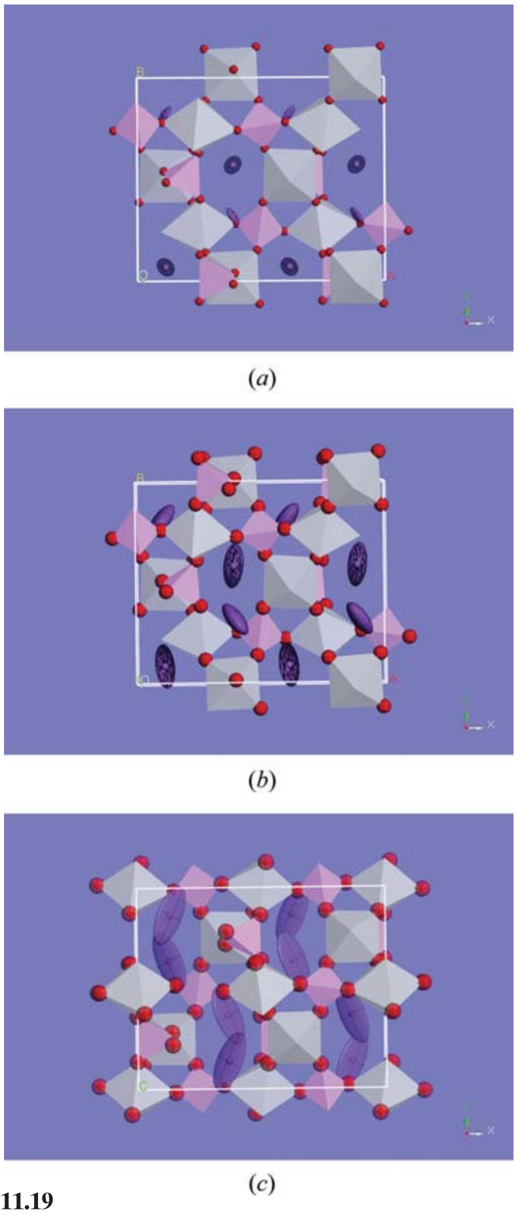

Figure 7.11.19

7.11.4. *In situ* studies

Even after several decades of experience, it is still true that *every* catalyst that we have studied under reaction conditions has had a different structure than under ambient conditions. A large part of catalyst research and development is the development of structure–activity correlations so that catalyst performance can be improved. Catalyst performance is (of course) measured under reaction conditions, but most analytical work is performed under ambient conditions. Developing a structure–activity correlation using the wrong structure is a bad business model, and is sure to limit the rate of catalyst development. It is virtually mandatory that *in situ* XRD studies be carried out, and XRD has an advantage over other analytical techniques in carrying out such studies. Such studies generally involve key intellectual property and are thus not often described in readily available publications.

A recent example of the importance of XRD to catalyst development is provided by US Patent 8697596 (Kaduk *et al.*, 2014) for metal-oxide catalysts for the conversion of lower alkane hydrocarbons, particularly for the ammoxidation of propane to acrylonitrile. The study was carried out under ambient conditions. The claims include a phase with the M1 crystalline structure, which has a unit-cell volume in the range 2250–2350 $Å^3$ and a crystallite aspect ratio in the range 0.7–2.0. The unit-cell volume is a proxy for changes in composition and subtle changes in the crystal structure of this phase. It does not take much of a structural change to significantly change the electronic properties at a catalyst site, so detailed structural studies of such catalysts provide the raw material for extensive quantum-chemical studies aimed at understanding the reactivity. The range of the aspect ratio of the crystallites reflects that crystallites that are too platy or needle-like yield poorer performance.

A noncatalytic example of an *in situ* study is the characterization of $KTiOPO_4$ (KTP) above and below the phase transition (Kaduk, 2000). The nonlinear optical properties of KTP have important applications in laser devices. KTP is used to generate 530 nm (green) light from 1060 nm infrared light produced by GaAs-pumped Nd/YAG solid-state lasers. KTP is also an ionic conductor, with large anisotropically enhanced conductivity along the [010] direction. This permits the synthesis of optical waveguides with reflecting walls parallel to (010).

KTP crystallizes in the orthorhombic space group $Pn2_1a$ at room temperature, and undergoes a high-temperature ferroelectric-to-paraelectric phase transition at 1207 K. KTP melts incongruently at 1343 K. Since KTP crystals are grown, and devices are fabricated, at temperatures near the phase transition, knowledge of the changes that occur at the transition would assist in the control of device properties.

Powdered KTP, prepared by solid-state synthesis from KH_2PO_4 and TiO_2, was pressed into pellets, and diffraction patterns were measured from 473 to 1323 K in flowing air using the 90° detector banks and the Miller furnace on the General Purpose Powder Diffractometer (GPPD) at the Intense Pulsed Neutron Source (IPNS) at Argonne National Laboratory. Patterns were measured in two sets of runs: one at a coarse temperature spacing to discern general features and a second closely spaced in temperature around the transition.

Neutron powder diffraction was used because the scattering contrast between the ions in KTP is well balanced (but is weighted towards titanium for X-rays) and because the transition temperature was not accessible on the single-crystal instrument at IPNS. The phase transition was crossed several times, and appeared to be reversible. No evidence of KTP decomposition was observed.

All data sets were first processed using the low-temperature $Pn2_1a$ model. The variation in the *a* and *c* lattice parameters was smooth, but there was a pronounced anomaly in the *b* lattice parameter at 1223 K. Given the uncertainties in the absolute temperature, this is close enough to the reported transition temperature of 1207 K to be identified with the phase transition.

Application of the *MISSYM* program from the *NRCVAX* system (Larson *et al.*, 1994) clearly indicated the presence of an additional *n*-glide perpendicular to *b* and a centre of symmetry. The transition is therefore analogous to that observed in $TlTiOPO_4$ at lower temperature using single-crystal techniques (Harrison *et al.*, 1990). Refinements using patterns collected below the transition were carried out in $Pn2_1a$ and those above the transition in *Pnna*.

In the KTP structure, alternating PO_4 tetrahedra and TiO_6 octahedra are linked by their vertices to form a two-dimensional network along the *a* and *b* axes, while the $(Ti1)O_6$ octahedra join

(P2)O_4 tetrahedra along *c*. The TiO_6 octahedra are linked together alternately *cis* and *trans* to form chains along [011] and $[01\bar{1}]$. The PO_4 tetrahedra are regular, while the TiO_6 octahedra are highly distorted, each containing one short (<1.75 Å) bond opposite a long bond (>2.10 Å) at room temperature. This distortion is believed to be the source of the large nonlinear optical coefficients of KTP. The potassium cations reside in channels parallel to [010] and [001], with windows defined by distorted hexagonal rings of O atoms.

In $Pn2_1a$ all of the atoms (two Ti atoms, two P atoms, two K atoms and ten O atoms) occupy general positions, while in *Pnna* the two independent Ti atoms occupy sites of 2 and $\bar{1}$ symmetry. The two P atoms remain independent and reside on twofold axes. The two independent K atoms become equivalent and occupy a general position. The ten O atoms reduce to five; in particular, the independent Ti—O—Ti chain O atoms O9 and O10 become equivalent.

The best measures of the phase transition are the metal–oxygen distances. The PO_4 tetrahedra remain virtually unchanged through the transition. The cations are intimately related to the physical properties of the material; replacing the potassium cations with sodium and rubidium lowers the melting temperature by >150 K.

The titanium coordinates change very little until the transition, when there is a sharp change to the high-temperature positions. The largest changes during the transition are in the *y* coordinates of the potassium cations; K1 moves nearly 0.7 Å and K2 by 0.3 Å to become equivalent. Changes in the Ti—O bond distances begin to occur at temperatures well below the transition temperature. At the transition, some changes in Ti—O distances are gradual (mostly involving Ti1), while others (principally involving Ti2) are sharp. To a good approximation, there are only low-temperature and high-temperature structures; intermediate structures are not observed.

In $Pn2_1a$ K1 is eight-coordinate and K2 is nine-coordinate, and the K—O distances span the normal range. In *Pnna* the single potassium is only five-coordinate and the distances are relatively short [according to bond-valence sum (BVS) calculations]. The anisotropic displacement coefficients of the potassium ions increase dramatically along *b* as the temperature increases (Fig. 7.11.19).

The phase transition appears to result not from a change in a single structural feature but from the sum of several smaller changes. The Ti—O and K—O distances begin to change at temperatures as low as 673 K, which is the result of both changes in the lattice parameters and potassium migration. At the transition, the accumulated changes are of sufficient magnitude to drive a sudden shift to the high-temperature structure. The transition is both displacive and second-order.

The observed structural changes are consistent with the changes in the optical and conduction properties and help to provide a firmer understanding of the properties of this complex structure. The practical significance of the work is to emphasize that high-quality single-domain crystals for device applications should be prepared at temperatures that are as low as possible to avoid imperfections caused by structural changes.

7.12. Powder-diffraction characterization of cements

M. A. G. Aranda, A. G. De la Torre and L. León-Reina

7.12.1. An introduction to cements and types of cements

The term cement may be used for almost any type of binder, with chemistry ranging from fully organic to totally inorganic. The oldest organic 'cements' were made from plant extracts such as starch or latex. The oldest pure inorganic cements were based on muds and subsequently on gypsum plasters. This dual nature of cements may be exemplified by the 'bone cements' used for medical applications, which range from totally organic (mainly based on polymethyl methacrylate) to totally inorganic, *e.g.* based on calcium phosphates. However, in this work we will focus on inorganic oxide-based hydraulic binders for construction applications. In this case, the cements are used as poorly soluble but highly reactive powders in water. The initial suspension, usually named fresh cement paste, firstly undergoes setting, and on hardening yields the hardened cementitious matrix. The use of water for achieving the hardening results in the term 'hydraulic binders' to highlight that the reaction of cement with water yields the concrete used for modern construction, which can even harden under water.

The world yearly consumption of concrete (http://en.wikipedia.org/wiki/Concrete), which is based mainly on Portland cement (http://en.wikipedia.org/wiki/Portland_cement), is well over 6 km^3, or more than 2.5 tonnes per person. Furthermore, in spite of their universal use, Portland cements are one of the most environmentally contentious materials. The worldwide production of cement, at more than 2×10^9 tonnes per year, accounts for approximately 6% of total anthropogenic CO_2 production. X-ray powder diffraction (XRPD) has two main uses in the cement industry: firstly, for improving the performance of Portland cements by measuring the phase assemblage of clinkers and cements and by determining and quantifying the chemical reactions during hydration, and secondly, for investigating new types of eco-cements, which release less CO_2 in their fabrication processes or in their life-cycle balance.

In this chapter, we highlight the uses of powder diffraction related to cements with selected examples. Firstly, we focus our attention on its uses for analysing different types of Portland clinkers, cements and blended cements. In this section, online Rietveld refinement in Portland cement plants is also discussed. Secondly, the uses of powder diffraction to study the chemistry and mineralogy of other cementitious materials are also highlighted. These cementitious materials include calcium aluminate cements, calcium sulfoaluminate, belite calcium sulfoaluminate cements (also known as sulfobelite cements), alkali-activated binders and supersulfated cements. The uses of Rietveld quantitative phase analysis for studying cement hydration reactions are addressed. It is becoming very important in this context for the analysis of blended cements. Initially, calcite, pulverized fly ash (PFA), blast furnace slag (BFS) and pozzolane additions were investigated. All of these materials are now being used industrially, and research is mainly devoted to other residues and by-products that can be blended with Portland cements. Powder diffraction has a bright future as most of the techniques developed for ordinary Portland cement (OPC) can be used to analyse new eco-cements: mainly sulfobelite, alkali-activated fly ashes and alkali-activated slags. Finally, selected examples of the use of synchrotron and neutron powder diffraction for characterizing cementitious materials, including their formation and degradation, will be discussed.

The uses of powder diffraction for the characterization of cementitious materials span phase identification (from the line positions and relative intensities) to microstructural studies (from the line widths). However, there is no doubt that quantitative phase analysis is the most important use of powder diffraction for analysing cements in order to understand/predict their performance. Moreover, although several methodologies have been reported to attain this objective, today Rietveld quantitative phase analysis (RQPA) is by far the most used technique. Hereafter, we will mainly deal with the use of RQPA applied to cementitious materials.

7.12.2. Rietveld quantitative phase analysis of cements

Quantitative phase analysis based on powder diffraction has already been discussed in this volume (see Chapter 3.9). Details of Rietveld quantitative phase analysis are also included in that chapter. It is worth noting that Hugo Rietveld did not envisage this use (Rietveld, 2010) in his two seminal papers (Rietveld, 1967, 1969). Two initial studies established the basis of RQPA (Hill & Howard, 1987; Bish & Howard, 1988). RQPA was first applied to the analysis of a Portland clinker six years later (Taylor & Aldridge, 1993).

Guidelines for Rietveld studies have been provided by McCusker *et al.* (1999). There are also two excellent articles arising from a round-robin study on quantitative phase analysis by powder diffraction (Madsen *et al.*, 2001; Scarlett *et al.*, 2002). Later, the results of a specific round-robin study on RQPA of Portland cements were reported (León-Reina *et al.*, 2009) and two review articles have been devoted to the RQPA of anhydrous Portland cements (Le Saoût *et al.*, 2011) and Portland cements, blended Portland cements and their hydration products (Aranda *et al.*, 2012). Based on these papers and others, this section gives some insights into RQPA of cements. As the analyses are becoming very complex (for instance hydration reactions of blended cements), a lot of care has to be exercised to carry out the best possible analysis. Two steps are carried out: obtaining crystal-structure information on all the phases that are likely to be present, and data analysis.

7.12.2.1. *Obtaining crystal-structure information*

Descriptions of the structures of each phase present in a cement must be included in the Rietveld control file. A thorough compilation of cement phases has been reported by Taylor (1997). Two updated compilations of crystal structures for RQPA of Portland anhydrous cements and hydration products have recently been reported (Le Saoût *et al.*, 2011; Aranda *et al.*, 2012). Sometimes there is more than one structural description available in the literature for a given phase. In this case, one possible methodology for selecting the most appropriate crystal structure is to carry out two (or more) RQPAs with the two (or more)

Copyright © 2019 International Union of Crystallography

reported structural descriptions. The structure selected should be that which gives the best fit based on the R_F factor, which is hopefully linked to a more accurate quantification, ideally based on known mixtures of the phases of interest. In addition to the main phases, other phases must be identified by searching for the extra peaks in the experimental pattern in the Powder Diffraction File (PDF, http://www.icdd.com). Once the phase has been identified, the crystal structure can be exported as a CIF from the PDF entry, or from one of the structural databases AMCSD (American Mineralogist Crystal Structure Database; http://rruff.geo.arizona.edu/AMS/amcsd.php), ICSD (Inorganic Crystal Structure Database; http://www.fiz-karlsruhe.de/icsd.html), COD (Crystallography Open Database; http://www.crystallography.net) or Pearson's Crystal Data (http://www.crystalimpact.com/pcd), or from another more specialized database (see Chapter 3.7). Finally, and mainly for solid solutions, site-occupation factor(s) for a given crystal structure must sometimes be adapted to describe a given stoichiometry.

If the crystal structures are not known, quantification of these phases may be achieved using reference patterns as '*hkl* phases' (Taylor & Aldridge, 1993), for instance with the *SIROQUANT* software. This approach has subsequently been expanded (Scarlett & Madsen, 2006) and is used in the cement industry (Chapter 3.9).

7.12.2.2. *Data analysis*

Once a powder pattern as free as possible of systematic errors has been recorded, Rietveld analysis must be carried out with the appropriate program and the control file. It is worth noting that the strong peak overlap in cements makes the analysis of phase peak-shape parameters critical. Working in reflection geometry, specimen rotation increases the particle statistics but it does not minimize preferred orientation. Some cement phases show this effect, which must be corrected, usually with the March–Dollase algorithm (Dollase, 1986), by using the appropriate axis. The preferred-orientation axes for some cement phases are [010] for gypsum, [001] for portlandite, [001] for the AFm family (defined below), [104] for the calcite family, [$\bar{1}$01] for alite-M_3 and [100] for ettringite. Spherical harmonics can also be used to model preferred orientation, but the severe peak overlap limits their use.

Hereafter, standard cement nomenclature will be used, *i.e.* C = CaO, S = SiO_2, A = Al_2O_3, F = Fe_2O_3, M = MgO, $\underline{S}$ = SO_3, $\underline{C}$ = CO_2, H = H_2O, K = K_2O and N = Na_2O. Hence, typical Portland cement phases such as alite (Ca_3SiO_5), belite (Ca_2SiO_4), tricalcium aluminate ($Ca_3Al_2O_6$), calcium aluminoferrite ($Ca_4Al_2Fe_2O_{10}$), gypsum ($CaSO_4{\cdot}2H_2O$), anhydrite ($CaSO_4$) and calcite ($CaCO_3$) are abbreviated as C_3S, C_2S, C_3A, C_4AF, $C\underline{S}H_2$, $C\underline{S}$ and $C\underline{C}$, respectively. Many cement compounds are not pure, stoichiometric phases but may incorporate many ions (Taylor, 1997; Le Saoût *et al.*, 2011).

New phases that appear during hydration must also be taken into account. They may be crystalline, such as portlandite, $Ca(OH)_2$ or CH, or amorphous/quasicrystalline phases such as calcium silicate hydrate gel (C-S-H gel in cement nomenclature to highlight its variable chemical composition, which changes with hydrating time, overall water content and even with the type of initial cement). AFm and AFt phases should also be defined. AFm is an abbreviation for 'alumina, ferric oxide, mono-sulfate' or 'Al_2O_3–Fe_2O_3–mono'; AFt is a similar abbreviation but for 'tri-sulfate' or 'Al_2O_3–Fe_2O_3–tri'. The AFm phase refers to a family of hydrated calcium aluminates based on the hydrocalumite structure, $Ca_4Al_2(OH)_{12}{\cdot}[Cl(OH)]{\cdot}6H_2O$. The archetypal AFm phase is $C_3A{\cdot}CaSO_4{\cdot}12H_2O$ or $Ca_4Al_2(OH)_{12}{\cdot}[SO_4]{\cdot}6H_2O$, known as kuzelite, but Al can be partly replaced by Fe, and SO_4^{2-} can be partly or fully replaced by OH^-, CO_3^{2-} and other anions (Pöllmann, 2006). By far the most common AFt phase is ettringite, which has the stoichiometry $C_3A{\cdot}3CaSO_4{\cdot}32H_2O$, also written as $Ca_6Al_2(SO_4)_3(OH)_{12}{\cdot}26H_2O$.

Programs for RQPA are listed in Chapter 6.1, and Rietveld programs are also listed on the CCP14 web site (http://www.ccp14.ac.uk/solution/rietveld_software/index.html). *GSAS* (Larson & Von Dreele, 1994; Toby, 2001) and *FULLPROF* (Rodríguez-Carvajal, 1993; Roisnel & Rodríguez-Carvajal, 2001) are the most widely used packages in academia. Many other packages can also be used for RQPA, for example *TOPAS*, *BGMN*, *AUTOQUANT*, *PDXL* and *HighScore Plus*.

7.12.3. Phase quantification of Portland cements

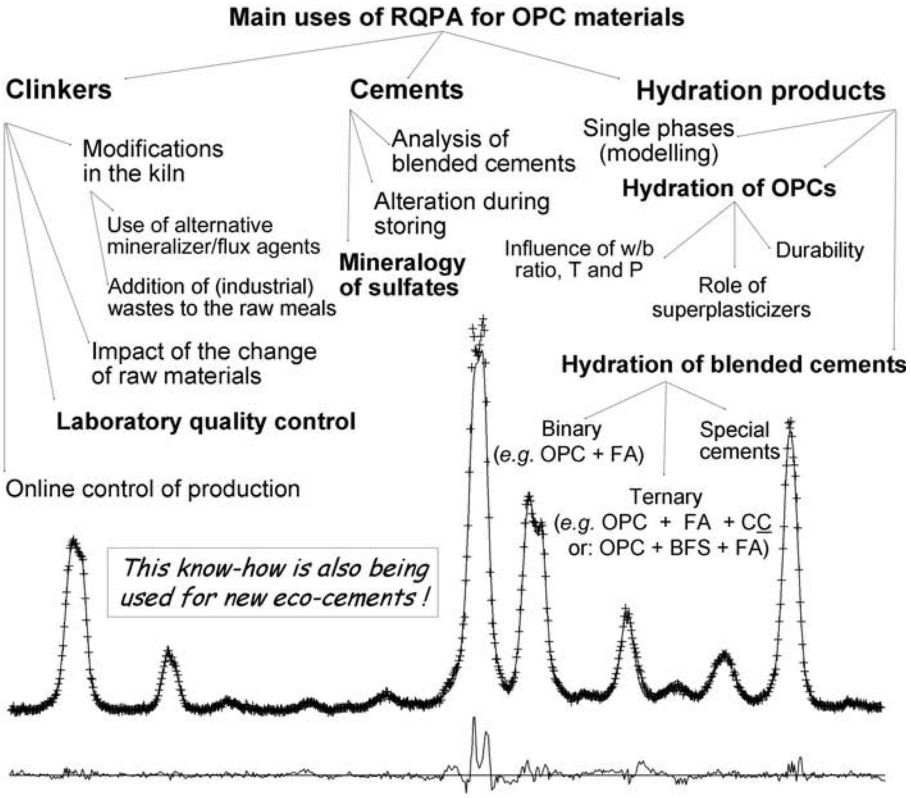
The output of an RQPA study for a mixture of crystalline phases with known structures is a set of the corresponding phase scale factors. The phase weight fractions can be derived from the phase scale factors using some approximations and methodologies.

(i) The simplest approach is the approximation that the sample is composed only of crystalline phases with known structures. This approximation eliminates the need to measure the instrument calibration constant and the sample mass absorption coefficient, and the phase scale factors can be directly transformed to phase weight fractions (Hill & Howard, 1987). However, if the sample contains amorphous phases, and/or some amount of unaccounted-for crystalline phases, the reported weight fractions will be overestimated.

(ii) A second, more experimentally demanding approach is to mix the sample with a crystalline standard in a known amount. This standard must be free of amorphous content, or at least its non-diffracting content must be known. The internal-standard method, coupled with RQPA, was first used in 1988 (Bish & Howard, 1988). The accuracy of RQPA using the internal-standard method for measuring amorphous content has also been studied (De la Torre, Bruque *et al.*, 2001). This procedure has recently been employed for certifying a standard (Cline *et al.*, 2011)

(iii) To avoid complications that may arise from mixing an internal standard with the sample, it is possible to use an external-standard method. This approach requires recording two patterns under identical diffractometer configurations and conditions. RQPA based on this method was proposed by O'Connor & Raven (1988) and has recently been applied to anhydrous cements (Jansen, Stabler *et al.*, 2011) and cement pastes (Jansen, Goetz-Neunhoeffer *et al.*, 2012; Jansen, Neubauer *et al.*, 2012). This methodology, which is also known as the G-method or K-method, consists of determining the diffractometer constant with an appropriate standard and using that diffractometer constant and the mass attenuation coefficient of the sample to convert the phase scale factors to weight fractions. This is an important limitation of the method as the precise chemical analysis of the sample must be independently obtained, for instance by X-ray fluorescence, to calculate the overall absorption coefficient.

The main uses of Rietveld quantitative phase analysis for extracting information on OPC materials are given in Fig. 7.12.1. These uses can be directly extended to other cementitious materials.



Main uses of RQPA for OPC materials
Clinkers
Modifications in the kiln
Use of alternative mineralizer/flux agents
Addition of (industrial) wastes to the raw meals
Impact of the change of raw materials
Laboratory quality control
Online control of production
Cements
Analysis of blended cements
Alteration during storing
Mineralogy of sulfates
Hydration products
Single phases (modelling)
Hydration of OPCs
Influence of w/b ratio, T and P
Durability
Role of superplasticizers
Hydration of blended cements
Binary (e.g. OPC + FA)
Special cements
Ternary (e.g. OPC + FA + CC or: OPC + BFS + FA)
This know-how is also being used for new eco-cements !

Figure 7.12.1
Main uses of Rietveld quantitative phase analysis for studying ordinary Portland clinkers, cements and hydration products. w/b is the water/binder ratio and 'raw meals' is a term used in the cement industry for raw material mixtures. [Reproduced with permission from Aranda *et al.* (2012).]

7.12.3.1. *Quantification of Portland clinkers*

The initial work on RQPA of a Portland clinker was published by Taylor & Aldridge (1993). Soon afterwards, other studies showed the advantages of this method, which does not require standards or calibration curves (Möller, 1995, 1998; Meyer *et al.*, 1998; Taylor *et al.*, 2000; Madsen & Scarlett, 2000). Initially, the studies were focused on OPC clinkers and were later expanded to different types of cements.

The main clinker phases are alite, belite and aluminate in white Portland clinkers and also ferrite in grey Portland clinkers. In addition, several other minor phases may be present: lime, periclase, arcanite, afthitalite and others. Two reviews of the phases present in OPC clinkers have been published (Le Saoût *et al.*, 2011; Aranda *et al.*, 2012). Several issues are discussed in these two reviews, including the selection of the alite polymorph, the implications of the Fe:Al ratio in ferrite quantification and the consequences of the existence of a solid solution in most clinker phases (resulting in small changes in the structure factors and densities of the analysed phases). As an example, Fig. 7.12.2 displays a selected region of the Rietveld plot for a typical commercial grey Portland clinker with the main peaks labelled. (This pattern and all the others displayed in this chapter were collected using strictly monochromatic Cu $K\alpha_1$ radiation. This is highly desirable to minimize peak overlap.) The inset in this figure shows the phase quantification under the first approximation stated above. (The sample is composed of 100% crystalline phases, which are all introduced in the Rietveld control file.)

The accuracy of RQPA of Portland clinker was investigated by De la Torre & Aranda (2003). The quantification of the amorphous/non-diffracting content in Portland clinkers has been a topic of research for a number of years. Suherman *et al.* (2002) carried out a thorough study using synchrotron and laboratory XRPD as well as internal- and external-standard approaches. Furthermore, selective dissolution and point-counting microscopy were also used with good results. The overall amorphous/non-diffracting contents for NIST reference clinker materials RM8486, RM8487 and RM8488 were ~6, ~11 and ~7 wt%, respectively. A subsequent analysis was dedicated to the study of the overall non-diffracting content in several commercial grey OPC clinkers and cements. The internal-standard method was used and an amorphous content close to 20 wt% was determined (Whitfield & Mitchell, 2003).

Another general use of RQPA is to study the role of mineralizing/flux agents in the kiln or the processing of industrial wastes in kilns by analysing the resulting clinker phase assemblage. The mechanism of action of the trace elements incorporated into the clinker is twofold depending on the amount of these elements (Herfort *et al.*, 2010).

(i) At low concentration, trace elements enter into the structure of the initial phases of the clinker as solid solutions (C_3Sss, C_2Sss, C_3Ass, C_4AFss).

(ii) At higher concentrations, the presence of new phases may be detected and quantified (Gineys *et al.*, 2011).

RQPA may help in both cases, initially by following the unit-cell variations of the solid solution(s) and secondly by quantification of the new phases. The implications of processing industrial waste(s) in Portland kilns have been studied by RQPA. As an example, this approach has been used to evaluate the effects of chromium and nickel additions to Portland clinker raw materials. The final goal was to better characterize the processing of galvanic sludge, which is the main hazardous solid waste produced by some metallurgical industries (Ferreira *et al.*, 2008).

7.12.3.2. *Quantification of Portland cements and blended cements*

Portland cements are formulated by adding a setting regulator to the Portland clinker. The sulfate phases added for this purpose may be gypsum or $C\underline{S}H_2$, hemihydrate $C\underline{S}H_{0.5}$ (also known as bassanite) and anhydrite $C\underline{S}$. Different types of Portland cements may have different additions, for instance calcite, $C\underline{C}$. Additionally, other highly amorphous materials may be added for blended cement and concrete production, such as BFS, PFA or pozzolane minerals. It must be kept in mind that these additions also contain some crystalline phases (for instance mullite or haematite) that must be quantified in blended cements. The reader is referred to the review of Aranda *et al.* (2012) for a full list of additional phases that may be present in blended Portland cements.

RQPA in OPCs can be used for a number of applications including (i) quantification of the crystalline phases in OPCs, (ii) to analyse the amount and role of sulfate-containing phases, (iii) to study the mineralogical phase assemblage in the materials used as addition(s) and (iv) to quantify all phases in blended OPCs, including the amorphous/non-diffracting content which is

important in BFS and PFA additions. As an example, Fig. 7.12.3 displays a selected region of the Rietveld plot for a typical type-II commercial Portland cement (Jackson, 1998) with the main peaks labelled, where in addition to the clinker phases, gypsum, bassanite and calcite are also quantified.

Commercial OPCs contain sulfate carriers as setting regulators in variable amounts. Gypsum (or other calcium sulfates) is added to the clinker during the milling process, where it may partially dehydrate to bassanite or even to soluble anhydrite III. Owing to the different solubilities of these phases, it is important to be able to characterize the mineralogical composition of sulfate in a cement system to reach an optimal and reproducible setting (Seufert *et al.*, 2009). The use of RQPA to determine the amounts of gypsum, bassanite and anhydrite in OPC has been demonstrated (Madsen & Scarlett, 2000; Walenta & Füllmann, 2004). The mineralogy of the sulfate source, as well as its content, is very important for the fluidity, setting and hydration of mortars and concretes (Tang & Gartner, 1988; Rössler *et al.*, 2008).

Today, supplementary cementitious materials (SCMs) are widely used in concrete, either in blended cements or added separately in the concrete mixer. The use of silica-rich materials influences the amounts and kinds of hydrates formed and thus the volume, the porosity and finally the durability of these materials (Lothenbach *et al.*, 2011). Therefore, it is easy to understand that the mineralogical phase assemblage in different common additions has been intensely studied, including BFS, PFA, bottom ash, metakaolin and others (Kumar *et al.*, 2008; Korpa *et al.*, 2009; Gonçalves *et al.*, 2009; De Weerdt *et al.*, 2011; Narmluk & Nawa, 2011). Furthermore, RQPA has also been used to characterize other less common additions such as drinking-water treatment-plant sludge (Husillos Rodríguez *et al.*, 2010) and natural zeolites (Snellings *et al.*, 2010).

7.12.3.3. *Online quantification of Portland clinkers and cements*

A full discussion of the different types of analyses that can be carried out in the cement industry (offline, at-line, online and in-line) is beyond the scope of this work. Very briefly, offline and at-line analyses are characterized by manual sampling followed by discontinuous sample preparation, measurement and evaluation. On the other hand, online and in-line analyses permit continuous process control. Typical examples of each type are (i) offline, trace-element analysis and microscopy; (ii) at-line, CaO determination by wet chemistry; (iii) online, X-ray fluorescence (XRF) and laboratory X-ray powder diffraction; and (iv) in-line, prompt gamma neutron activation analysis. In addition to the use of XRF to monitor the elemental composition of the different materials, RQPA may be carried out online to provide mineralogical analyses of clinkers and cements. Other techniques that also provide mineralogical analysis, such as optical microscopy, cannot be easily implemented online, although they may yield very good offline results (Stutzman, 2012).

Online RQPA systems, where automatic data sampling is coupled to reproducible sample preparation (including milling and pressing in dedicated robot systems) and data collection in optimized powder diffractometers, is becoming widespread. After powder-diffraction data have been collected in a predefined 2θ range, resident automatic software carries out the analysis in a sequence of previously defined steps. It should be emphasized that the program computes what it is indicated in the control file(s), which is generally adapted to the specific sample (clinker or cement) in order to increase the accuracy of the analyses. Usually, each variable parameter has an upper and lower limit, which ensures the robustness and stability of the analysis. The reader is referred to Scarlett *et al.* (2001), Fullmann & Walenta (2003) and Paul *et al.* (2004) for further details. Finally, there is a review dealing with the analysis of building materials by powder diffraction in industry by Meier & Anderson (2012).

7.12.4. Quantification of other cementitious materials

There are many type of cementitious materials in addition to Portland cements. Here, we briefly discuss some important systems and give selected examples of powder-diffraction studies.

7.12.4.1. *Calcium aluminate cements*

The term calcium aluminate cements (CACs) covers a range of inorganic binders characterized by the presence of monocalcium aluminate ($CaAl_2O_4$, CA) as their main constituent. According to chemical composition, CACs are classified as (i) standard low alumina (36–42 wt% Al_2O_3 and 12–20 wt% Fe_2O_3 + FeO), (ii) low alumina, low iron (48–60 wt% Al_2O_3 and 1–3 wt% Fe_2O_3 + FeO), (iii) medium alumina (65–75 wt% Al_2O_3 and <0.5 wt% Fe_2O_3 + FeO) and (iv) high alumina ($\geq$80 wt% Al_2O_3 and <0.2 wt% Fe_2O_3 + FeO) (Pöllmann, 2012). This classification can be reduced to two groups: grey/black CACs and white CACs. Grey/black CACs consist mainly of CA, mayenite ($C_{12}A_7$), melilite [a gehlenite (C_2AS)–akermanite (C_2MS_2) solid solution], β-C_2S, pleochroite ($Ca_{20}Al_{32-x}Fe_xSi_xO_{68}$), ferrite ($C_4AF$), wüstite (FeO) and perovskite (CT). White CACs mainly contain CA, calcium dialuminate (CA_2) and α-alumina. Thus, some CACs may contain more than nine phases, and selective dissolutions to enrich minor phases are advisable to identify them. Furthermore, most of these phases are solid solutions, which may cause slight modifications in peak positions and relative intensities. Rietveld quantification is related to phase density and therefore the exact chemical compositions are needed even for minor phases. This phenomenon is especially relevant when analysing grey CACs, as iron can be distributed among different phases. For instance, CA may form a solid solution with iron ($CaAl_{2-2x}Fe_{2x}O_4$; Guirado & Galí, 2006). However, the use of laboratory XRPD is not advisable for refining the Al^{3+}/Fe^{3+} occupation factor(s). This ratio should be constrained to published values or determined by another technique(s), such as scanning electron microscopy with X-ray microanalysis. In any case, the unit-cell parameters must be optimized. The amount of iron in ferrite and pleochroite phases can also be variable. A detailed review of the mineralogy of these systems and a complete compilation of the crystal structures required to perform Rietveld refinement can be found in Pöllmann (2012) and Guirado & Galí (2006). Fig. 7.12.4 shows a selected range of a Rietveld plot for a grey CAC with the main peaks labelled and the RQPA result shown in the inset.

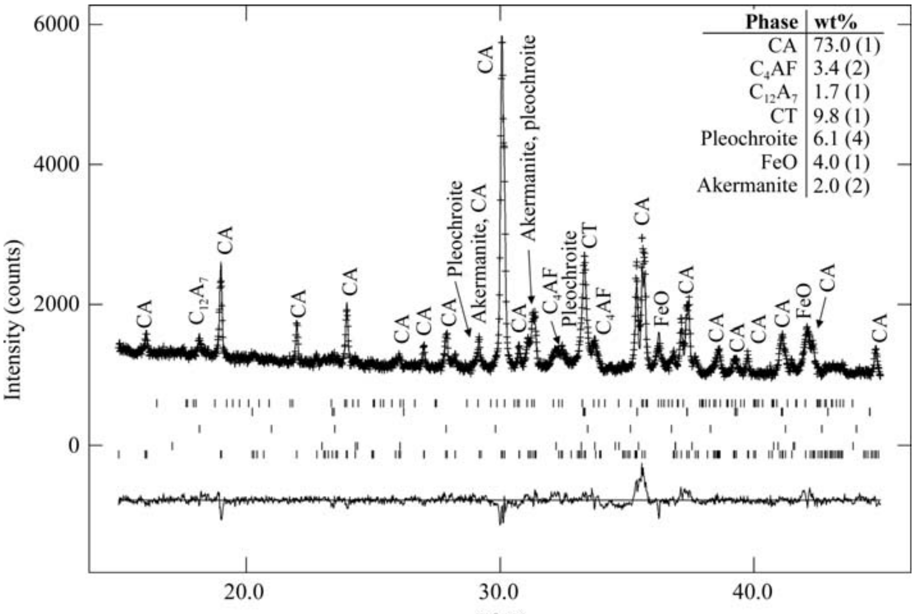

Figure 7.12.4

Selected region of a Rietveld plot using Cu $K\alpha_1$ radiation for a commercial calcium aluminate cement with the main peaks labelled. The RQPA result is shown in the inset.

7.12.4.2. *Calcium sulfoaluminate cements*

Laboratory-prepared calcium sulfoaluminate (CSA) cements have been known since the 1960s (Metha & Klein, 1965). Industrial cements based on this system were developed in the 1970s in China (Zhang *et al.*, 1999) and they are known as 'the third series cement of China'. CSA cements are characterized as containing high amounts of yeelimite, also called Klein's salt or tetracalcium trialuminate sulfate ($C_4A_3\underline{S}$). Two recent reviews of this type of cement have appeared (Juenger *et al.*, 2011; Aranda & De la Torre, 2013).

Binders based on CSA cements, or blended with OPC, are employed for quick repairs and pre-cast products or floor concrete applications. These binders have been used and standardized in China, and in spite of a lack of standards concerning these special cements, their manufacture has recently been started by several European companies (Álvarez-Pinazo *et al.*, 2012). Moreover, in recent years research on these cements has increased because of their low environmental impact, as the CO_2

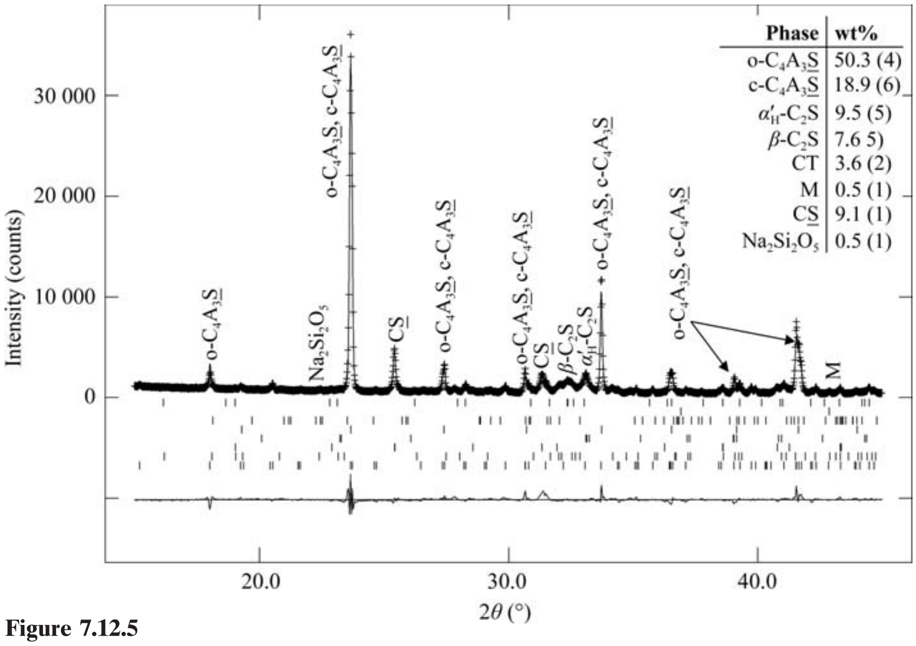

Figure 7.12.5

Selected region of a Rietveld plot using Cu $K\alpha_1$ radiation for a commercial calcium sulfoaluminate cement with the main peaks labelled. The RQPA result is shown in the inset.

emissions in their fabrication process are strongly reduced when compared to ordinary Portland cement production.

The raw material composition will determine the CSA clinker phase assemblage, containing $C_4A_3\underline{S}$ with other phases such as β-C_2S, ferrite, anhydrite, perovskite or gehlenite. Again, minor elements may form solid solutions. Recent work on yeelimite-containing cement matrices has reported several RQPAs for commercial cements (Álvarez-Pinazo *et al.*, 2012).

About 15–25 wt% sulfate carrier is interground with CSA clinker to tailor the setting time, strength development or volume stability of the final concrete. The most common sulfate carriers are gypsum, bassanite and anhydrite. On the other hand, the excess of anhydrite present in some CSA clinkers (formed in the clinkering process) is the less-soluble anhydrite II, which can be identified and quantified jointly with other sulfate carriers. Furthermore, ternary binders composed of OPC, CSA and anhydrite have also been studied by powder diffraction in order to determine the impact of variations of the OPC:CSA:$C\underline{S}$ ratio on the hydration process (Pelletier *et al.*, 2010). Fig. 7.12.5 shows, as an example, a selected region of a Rietveld plot for a commercial CSA clinker with the main peaks labelled and the RQPA results included as an inset.

7.12.4.3. *Calcium sulfobelite cements*

A new type of yeelimite-containing cement is emerging because of its environmental benefits. The term belite calcium sulfoaluminate (BCSA) is reserved for cements arising from clinkers with C_2S (belite) as the main phase and intermediate $C_4A_3\underline{S}$ contents. The most common formulation of BCSA clinkers, also known as sulfobelite, consists of β-C_2S, $C_4A_3\underline{S}$ and C_4AF (Janotka & Krajči, 1999; Adolfsson *et al.*, 2007). The lower CO_2 emission of this type of cement has been highlighted and its possible composition has been reviewed (Gartner & Macphee, 2011; Aranda & De la Torre, 2013).

Most BCSA clinkers contain ~55 wt% C_2S, ~25 wt% $C_4A_3\underline{S}$ and ~20 wt% C_4AF. These are iron-rich BCSA cements, also termed BCSAF. These binders develop high mechanical strengths at early ages because of the presence of yeelimite, which reacts rapidly with water to give ettringite. On the other hand, the reactivity of β-belite with water is very slow, and minor elements are included in the raw mixture to stabilize more reactive α-forms of C_2S (Gartner & Li, 2006; Cuberos *et al.*, 2010). Active sulfobelite cements have been successfully prepared in the laboratory (Cuberos *et al.*, 2010; Álvarez-Pinazo *et al.*, 2012). In these studies, the main goal was quantitative analysis using the RQPA methodology of α'_H-C_2S polymorph stabilization by borax addition. This polymorph hydrates much faster than β-C_2S. Fig. 7.12.6 shows Rietveld plots of an active BCSAF with 2.0 wt% B_2O_3 added as borax. The crystal structure of α'_H-C_2S doped with sodium and boron has been revised (Cuesta *et al.*, 2012) and better fits the α'_H-C_2S present in active sulfobelite cements.

7.12.4.4. *Materials with pozzolanic activity*

The term pozzolanic activity covers those reactions occurring between aluminosilicates and an alkaline solution, for instance lime and water. The use of aluminosilicates has an important sustainable impact as they are among the most abundant minerals at the surface of the Earth. As previously mentioned in Section 7.12.3.2, supplementary cementitious materials (SMCs) are used as active additions either to cements or concretes to give a pozzolanic reaction, yielding final materials with special properties (Snellings *et al.*, 2010). Alkali-activated binders are composed of a solid aluminosilicate powder mixed with an alkaline activation solution. The most common industrial sources are PFA from thermal plants and BFS from the pig-iron industry. The chemistry of the hydration processes is closely related to that of Portland cements blended with SMC materials and to alkali-activated binders, which will be introduced in the next section. Materials

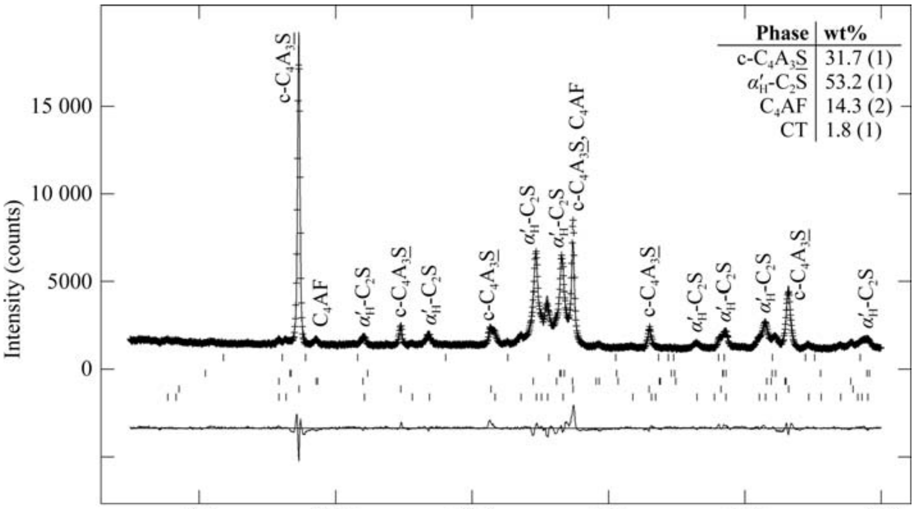

Figure 7.12.6

with pozzolanic activity should be fully characterized in order to understand and predict their final performance. Most of them are highly amorphous, containing some crystalline phases, such as mullite or haematite (Winburn *et al.*, 2000; Fernández-Jiménez *et al.*, 2006*a*). The quantification of the amorphous content in these materials can be approached by internal- or external-standard methods. Fig. 7.12.7 shows the Rietveld plot for a PFA with 85 wt% amorphous content, determined using the G-method with Si as an external standard. The initial direct Rietveld analysis, normalized to 100% of crystalline phases, gave 56.0 (3) wt% mullite, 35.2 (3) wt% quartz, 3.0 (2) wt% haematite, 3.4 (2) wt% magnesioferrite spinel, 1.0 (1) wt% lime and 1.5 (1) wt% periclase.

7.12.4.5. *Other cements*

There are several other alternative cement binders and there is not space here to treat all possible systems. However, some will be mentioned: supersulfated cements, partially prehydrated C-S-H-based binders and magnesium-based cements.

Supersulfated cements are generally composed of 70–90 wt% granulated BFS, 10–20 wt% calcium sulfate and <5 wt% of an alkaline activator, usually OPC or Portland clinker (Juenger *et al.*, 2011). Full mineralogical characterization of supersulfated cements by RQPA includes the quantification of amorphous and crystalline phases and the nature and content of the sulfate carrier (Adolfsson *et al.*, 2011). Granulated BFS with a high content of CaO, MgO and especially Al_2O_3 is suitable for the manufacturing of supersulfated binders and commonly contains very small amounts of crystalline phases. Gypsum and anhydrite are widely used as sulfate carriers, although bassanite or even secondary sulfate sources, such as phosphogypsum, may be added. With respect to the alkaline activator, there are some reports of the use of calcium or potassium hydroxide or sodium carbonate instead of OPC clinker. These materials are attracting attention as alternative, environmentally friendly binders with good durability in chemically aggressive environments. Moreover, there is a European Standard for supersulfated cements (EN 15743) which allows its use under specific conditions.

Celitement is a partially prehydrated C-S-H-based binder (Stemmermann *et al.*, 2010). This material is produced in two steps: crystalline α-C_2SH is first produced and is then interground with silica-rich filler. This step is essential to produce a reactive coating on the filler particles.

Magnesium-based cements are far from new: they were patented in 1867. These materials are composed of MgO which is hydrated with concentrated solutions of magnesium chloride (known as Sorel cements), magnesium sulfate or a soluble phosphate. All of these cements use MgO powders from the decarbonation of $MgCO_3$. The hydration reactions strongly depend on the microstructure and mineralogy of the MgO, which can be studied by laboratory XRPD jointly with other techniques such as scanning electron microscopy. Very recently, Novacem has presented a new approach to magnesium-based cementitious materials. The fundamental innovation consists of the extraction of MgO from magnesium silicate rocks by carbonation at high pressure. This binder is considered as a carbon-negative cement: not only are CO_2 emissions recycled back in the process, but also some atmospheric CO_2 may be absorbed (Gartner & Macphee, 2011).

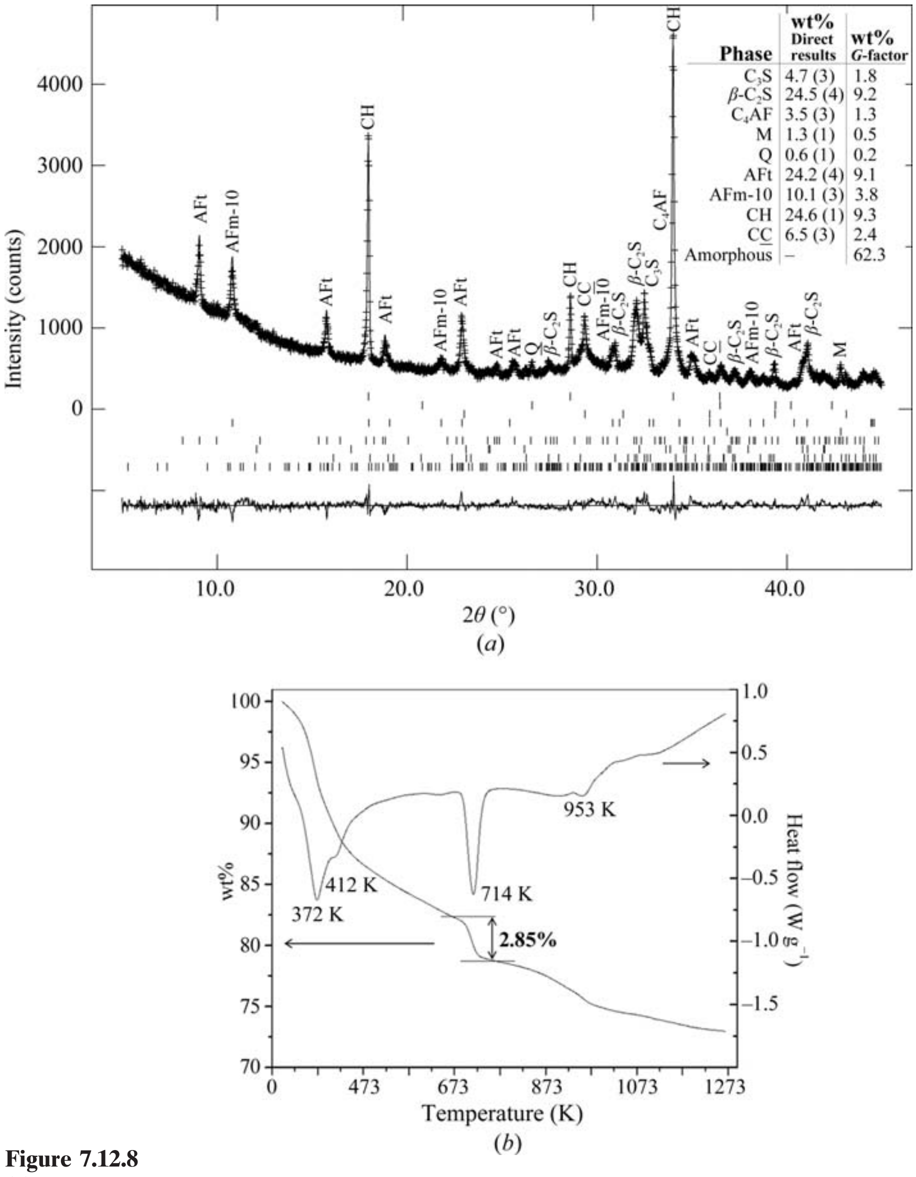
7.12.5. Powder-diffraction studies on the hydration of cements

RQPA has been employed to investigate the hydration products of several types of cements, OPC and alternative cementitious materials. The hydration reactions have been studied in order to monitor the evolution of hydrous phases and to understand phase evolution, including the determination of the amorphous phase during the hydration reactions (Aranda *et al.*, 2012). The roles of several variables (water content, sulfate source and amount, role of admixtures and superplasticizers *etc.*) must be studied as they strongly influence mechanical strengths and chemical durability. A full discussion of the different systems that can be addressed is beyond the scope of this work. We highlight selected typical examples.

7.12.5.1. *Hydration studies of Portland cements and blended Portland cements*

Laboratory X-ray powder diffraction RQPA has been used to study the hydration reactions of commercial OPC in reflection (Scrivener *et al.*, 2004) and transmission (Mitchell *et al.*, 2006) geometries. Both methodologies allow the study of new phases arising during hydration; the results can be successfully compared to those obtained from thermal analysis and electron microscopy. It is important to underline the benefits of the transmission geometry as more particles are measured, which yields more reliable quantitative results along with a decrease in preferential orientation.

New phases appear during the hydration of OPCs. The mineralogy of the hydrate compounds is variable and it may depend upon the additions in blended cements (Matschei & Glasser, 2010). Many hydrate phases may be present in a given sample. A review of calcium silicate hydrates is given by Richardson (2008). The reader is referred to a review on OPC and RQPA for a list of phases that may be present in Portland



Phase	wt% Direct results	wt% G-factor
C_3S	4.7 (3)	1.8
β-C_2S	24.5 (4)	9.2
C_4AF	3.5 (3)	1.3
M	1.3 (1)	0.5
Q	0.6 (1)	0.2
AFt	24.2 (4)	9.1
AFm-10	10.1 (3)	3.8
CH	24.6 (1)	9.3
$C\underline{C}$	6.5 (3)	2.4
Amorphous	–	62.3

Figure 7.12.8

(*a*) Selected region of a Rietveld plot using Cu $K\alpha_1$ radiation for a hydrated Portland cement after 13 d. RQPA results, both direct and those obtained from the external-standard G-method, are shown as an inset table. (*b*) The thermal-analysis curves (thermogravimetric and differential thermal analysis) for this paste with the weight loss owing to portlandite, CH, highlighted.

cement pastes (Aranda *et al.*, 2012). Fig. 7.12.8(*a*) displays the Rietveld plot for an OPC hydrated sample showing a rich phase assemblage. This paste was fabricated with a water-to-cement weight ratio of 0.5 and hydrated for 13 d. The reactions were then stopped with acetone and the specimen was washed with ether. In addition to some remaining anhydrous cement phases, new crystalline hydrates appear, *e.g.* CH, AFt and AFm (see Fig. 7.12.8*a*). Additionally, a small amount of calcite arising from the carbonation of portlandite is also present. The peaks in the pattern are labelled to easily indentify each crystalline phase. In addition to the crystalline phases, a large amount of amorphous phase is measured by the G-method, which is mainly from the C-S-H gel. Finally, it is worth noting that accuracy of the analyses is always of the utmost importance. Fig. 7.12.8(*b*) shows the thermal-analysis data for this paste and the portlandite weight loss (2.85 wt%) indicates 11.7 wt% $C\underline{H}$ in the paste. This value is not far from that determined in the powder-diffraction analysis, 9.3 wt%, which indicates that the accuracy is within the region of ~2 wt%.

The process of the hydration of OPCs is commonly subdivided into several periods. These periods include early hydration and hydration after several days. The study of early and very early hydration processes is not easy using laboratory equipment and sometimes requires the use of temperature and humidity chambers (Scrivener *et al.*, 2004). The hydration of an OPC over 28 d has been studied by RQPA using the external- and internal-standard methods in order to determine the amount of amorphous content (Le Saoût *et al.*, 2007). The authors also studied the role of isopropanol in stopping the hydration reaction. The early hydration of cements has been also studied by laboratory XRPD using reflection geometry at defined temperatures and with different water:cement ratios (Hesse *et al.*, 2008, 2009). The heat flow measured by calorimetric experiments in the early hydration of OPCs was successfully compared with that calculated from RQPA results using the external-standard G-method (Jansen, Bergold *et al.*, 2011).

The hydration reactions of alkali-poor and alkali-rich OPCs have also been followed by RQPA. *In situ* laboratory XRPD for monitoring cement hydration has been used to study Portland cement clinkers consisting of alite and aluminate doped with different amounts of Na_2O (Wistuba *et al.*, 2007). Significant differences during early hydration have been measured as a consequence of the presence of syngenite when the alkali content is high.

The uses of RQPA to study hydration processes have been expanded from the hydration of model systems (Bellmann *et al.*, 2010) to blended cements and the role of admixtures and superplasticizers. RQPA has been used to analyse the hydration progress of cement pastes prepared by adding BFS and limestone powder (Hoshino *et al.*, 2006). Selective dissolution was employed to distinguish between the amorphous content coming from BFS and the newly formed C-S-H gel. A detailed study was carried out to quantitatively explain the effect of water curing on the compressive strengths of cement pastes containing PFA (Termkhajornkit *et al.*, 2006). A complete study using RQPA together with thermogravimetry, scanning electron microscopy and isothermal calorimetry was developed in order to understand the hydration mechanisms of ternary blended Portland cements containing fly ash and limestone powder (De Weerdt *et al.*, 2011). The authors studied the time evolution of all of the phases during hydration in order to understand the pozzolanic effect and the variations in chemical shrinkage. Furthermore, selective dissolution and RQPA have been employed to understand the effect of fly ash on the kinetics of OPC hydration at different curing temperatures (Narmluk & Nawa, 2011).

7.12.5.2. *Hydration studies of alternative cementitious materials*

It is not possible to describe in detail all of the studies on the hydration of alternative cementitious materials. Therefore, we give a summary of some selected research. RQPA has been applied to the hydration of cementitious materials such as CSA/

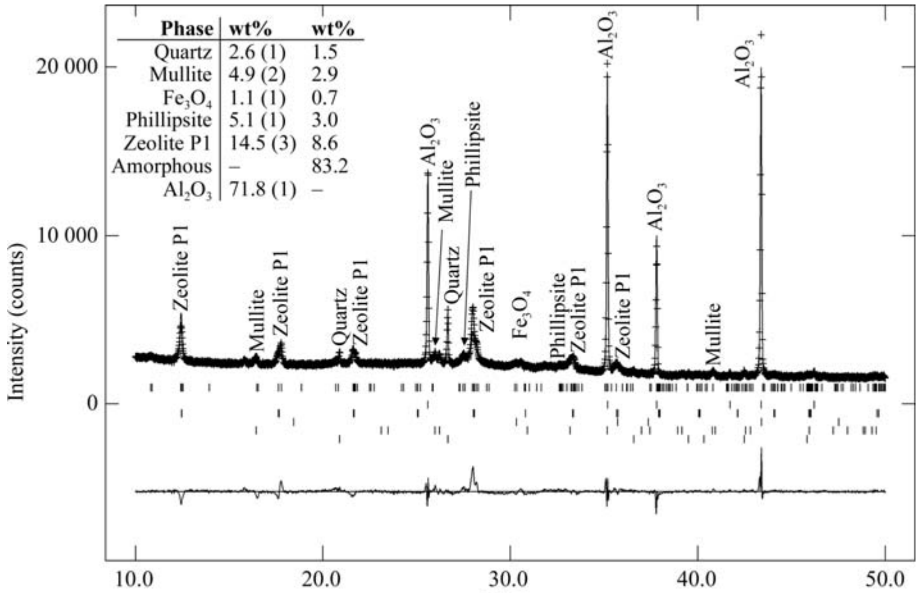


Figure 7.12.9
Selected region of a Rietveld plot using Cu $K\alpha_1$ radiation for an alkali-activated fly ash mixed with Al_2O_3 as an internal standard (weighed: 29.96 wt%) after 180 d of hydration. The RQPA results are given in the inset, with the first column being the direct analysis (normalized to 100% of crystalline phases including the standard) and the second column showing the analysis including the amorphous content and without the internal standard.

BCSA cements (Alesiani *et al.*, 2008; Cuberos *et al.*, 2010; Martín-Sedeño *et al.*, 2010; Morin *et al.*, 2011). These studies have confirmed the higher reactivity of the α-forms of C_2S and have determined the mechanism of hydration, as well as the influence of admixtures.

Alkali-activated cement hydration has also been characterized by RQPA jointly with other techniques (Criado *et al.*, 2007; Fernández-Jiménez *et al.*, 2006*b*). These studies not only quantify the crystalline zeolites formed during hydration as a function of the activator used, but also discriminate between the initial amorphous phases present in fly ashes and the sodium aluminosilicate gel formed as a consequence of activation. Fig. 7.12.9 shows a selected range of a Rietveld plot of an activated fly ash after 180 d of hydration mixed with α-Al_2O_3 as an internal standard to quantify the amorphous content. Activation was performed with a mixture of sodium silicate and sodium hydroxide ($SiO_2/Na_2O = 1.17$). Quantitative phase analysis, including amorphous content, is also shown as an inset to Fig. 7.12.9.

Laboratory XRPD has also been used to characterize the hydration products of the prehydrated C-S-H-based binder Celitement. The main hydration products of this type of cement are ettringite and C-S-H, and (as minor phases) AFm-type compounds (Gruskovnjak *et al.*, 2011). The hydration reactions of magnesium-based cement are complex, as several binary hydrated phases, such as $5Mg(OH)_2{\cdot}MgCl_2{\cdot}8H_2O$, may be present in the hydrated matrix (Ozer *et al.*, 2011). However, there is currently a dearth of applications of the RQPA methodology to these systems.

7.12.6. The use of synchrotron and neutron powder diffraction for studying cements

The first application of high-energy (λ = 0.442 Å) synchrotron X-ray powder diffraction (SXRPD) in Debye–Scherrer (transmission) configuration was for the accurate RQPA of a commercial OPC clinker (De la Torre, Cabeza *et al.*, 2001). The high-resolution nature of SXRPD allowed determination of the polymorphism of the phase without selective dissolution. Furthermore, the use of capillaries of 1.0 mm in diameter in the synchrotron study allowed a large amount of sample to be tested, which yielded reproducible diffraction intensities and thus accurate RQPA results. However, the expense of synchrotron measurement only allows its use for very special problems or for proof-of-principle experiments. The high-resolution data provided by synchrotron radiation established the coexistence of an alite phase in some commercial grey OPC clinkers for a range of magnesium contents (De la Torre *et al.*, 2005) and a change in alite crystal form as a function of the magnesium content (De la Torre *et al.*, 2008). Neutron powder diffraction (NPD) has also been used for the RQPA of clinkers (Pritula *et al.*, 2004). Furthermore, NPD, SXRPD and laboratory studies have been used to study the NIST reference clinker material RM8488 (Peterson *et al.*, 2006).

SXRPD (and NPD) has been used to study the crystal structures of selected phases in cements as well as relevant phase changes (and transitions) as a function of external variables including temperature, pressure, hydration, CO_2 partial pressure (carbonation), electrical field *etc.* We highlight some structural studies carried out using SXRPD for relevant cement phases (Yamazaki & Toraya, 2001; De la Torre *et al.*, 2002; Rapin *et al.*, 2002; Peterson *et al.*, 2004; Martucci & Cruciani, 2006; Garbev *et al.*, 2008; Mesbah *et al.*, 2011).

SXRPD has also been used, coupled to RQPA, for more demanding applications such as following *in situ* clinkering reactions at high temperatures (up to 1773 K). The preheated raw material is loaded into a platinum tube and high-energy synchrotron X-rays ($\lambda \simeq 0.30$ Å) are used to penetrate the holder and to obtain accurate intensities. This experimental procedure has been employed to study the clinkering reactions of belite cements (De la Torre *et al.*, 2007) and sulfobelite cements (De la Torre *et al.*, 2011).

SXRPD has also been widely used, coupled to RQPA, to characterize the hydration reactions of different types of cements. Early studies based on energy-dispersive low-resolution SXRPD are not reviewed here. RQPA based on *in situ* monochromatic SXRPD was used to monitor the evolution of hydrous phases during early hydration with a time resolution of 10 s (Weyer *et al.*, 2005). A related study but with lower time resolution (minutes) studied the hydration process in synthetic clinker phases (C_3A and C_4AF) and non-commercial OPCs (Merlini *et al.*, 2007). SXRPD has also been used to monitor the evolution of ettringite in a C_3A–gypsum synthetic mixture and in commercial OPCs during the first hours of hydration (Merlini *et al.*, 2008). *In situ* synchrotron RQPA has also been carried out to study the early hydration of class-A and -H oil-well Portland cements (Jupe *et al.*, 2007, 2008), active belite cement (Cuberos *et al.*, 2009), aluminium-rich belite sulfoaluminate cements (Martín-Sedeño *et al.*, 2010), and pozzolanic reactions in blended cements (Snellings *et al.*, 2010). Synchrotron radiation may also be used in more sophisticated types of characterization. For instance, high-energy synchrotron X-ray microdiffraction was used to quantify the orientation distribution of ettringite crystals. Diffraction images were analysed using the Rietveld method to obtain information on textures within thin slabs of mortars (Wenk *et al.*, 2009).

The composition and microstructural changes of cement pastes under a heating and cooling cycle have also been monitored by NPD. We highlight a study in which the heating rate, the state of the sample (block or ground) and the type of cement were varied (Castellote *et al.*, 2004). NPD was subsequently used to study the phase-composition changes of cement pastes during accelerated carbonation experiments (Castellote *et al.*, 2008). The same group used SXRPD to study the degradation over time of cement pastes, which was simulated by applying an electrical field (Castellote *et al.*, 2002).

SXRPD is very well suited for high-pressure studies, which are key to determining the bulk modulus values of relevant hydrate phases (Clark *et al.*, 2008; Oh *et al.*, 2011, 2012; Moon *et al.*, 2012). Energy-dispersive SXRPD was also used to study the hydration (hydrothermal) reactions of commercial oil-well cements, alone or with additions of silica flour and of corundum (Colston *et al.*, 2005; Meller *et al.*, 2007).

Finally, new techniques based on synchrotron radiation are emerging in which powder diffraction is combined with imaging tools in order to extract more information. For example, X-ray diffraction microtomography has been employed to study the hydration of Portland pastes (Artioli *et al.*, 2010; Valentini *et al.*, 2011) and of calcium sulfoaluminate pastes (Gastaldi *et al.*, 2012).

7.12.7. Conclusions and outlook

Powder diffraction coupled with Rietveld quantitative phase analysis is increasingly being used for the characterization of cementitious materials. Initially it was mainly used to measure anhydrous Portland clinkers and cements, but it is now used to analyse many types of hydrated products. RQPA is increasingly being used for studying the hydration reactions of blended cements. The number of residues and by-products (with different chemical and mineralogical compositions) that can be blended with Portland cements is large and expanding. In addition, research on new types of eco-cements is expanding rapidly. Here, powder diffraction has the brightest future, as most of the techniques developed for characterizing OPC samples are being adapted to analyse these new eco-cements.

However, as the complexity of the studied cementitious materials increases (some samples contain more than nine crystalline phases) the powder averaging for all phases becomes critical. Powder averaging may be increased by recording full two-dimensional patterns, but the current technology does not provide the highest-resolution powder patterns. An alternative approach is to use highly penetrating X-rays. Therefore, we expect molybdenum-radiation diffractometers to be used for the RQPA of very complex samples. However, peak overlap will be higher with Mo $K\alpha$ radiation than with Cu $K\alpha$ radiation as the powder pattern is compressed into a smaller range of 2θ (because the wavelength is shorter), so an incident-beam monochromator is needed to select only Mo $K\alpha_1$ radiation to minimize peak overlap. The effect of (possible) transparency issues should also be investigated. Mo $K\alpha$ incident-beam monochromator(s) coupled with fast detectors are likely to drive the next breakthrough in cement analysis.

Finally, we expect to see a large increase in the use of the external-standard method for hydration cement studies. This approach has two important advantages over the internal-standard method: (i) no dilution of low-content phases occurs and (ii) the possible interference of the standard with the hydration reactions is avoided.

Data for the studies described here are available from Zenodo (records 890585, 1027759 and 1147630).

This work was supported by Spanish research grant MAT2010-16213, which is co-funded by FEDER from the European Union.

7.13. Powder diffraction of superconductors

Qingzhen Huang

7.13.1. Introduction

In this chapter, we shall focus on the application of the powder-diffraction method to research on superconductivity, with an emphasis on using this method to obtain structural information. A great number of valuable research reports and review articles on this topic have been published in the past few decades and have been used as primary information sources in preparing this chapter. Because of space restrictions, however, only a limited number of these are given as references.

7.13.1.1. *Properties of superconductors*

Zero electrical resistance. Contrary to what happens in insulating, semiconducting and conducting materials, a superconductor in its superconducting state shows zero resistance to a flow of electrical current (Fig. 7.13.1*a*). T_c denotes the critical transition temperature below which the material transforms from a non-superconducting (NSC) state to the superconducting (SC) state.

Diamagnetism. Another distinguishing characteristic of superconductors is that they show diamagnetic behaviour below T_c. Figs. 7.13.1(*b*) and (*c*) show the critical field *versus* temperature diagrams for type-I and type-II superconductors, respectively (Lynn, 1990). For a type-I superconductor, the magnetic field is screened from the interior of the sample until a critical field H_c is reached; above H_c the superconductivity is quenched and the magnetic field penetrates uniformly into the material. For a type-II superconductor, when the applied magnetic field is less than the lower critical field H_{c1} it acts as a perfect diamagnet (like a type-I superconductor) and the field is screened from the interior bulk of the material, as shown in the SC1 region in Fig. 7.13.1(*c*). In the SC2 region above a critical field H_{c1}, the system is partially penetrated by the field and the material remains superconducting. The field increasingly penetrates the system as the applied field is increased, until finally above the second critical field H_{c2} the superconducting state is destroyed.

7.13.1.2. *A brief description of superconducting systems*

Kamerlingh Onnes (1911) first discovered superconductivity, observing that the direct current (DC) resistance of pure Hg metal droped to zero below 4.15 K. In the following years, superconductivity was found in elements, alloys, intermetallics and compounds. Bednorz & Muller (1986) reported the possible existence of a T_c of ~30 K in the La–Ba–Cu–O system. This was the first time that T_c was found to be higher than 23.2 K, previously reported for the best superconducting intermetallic Nb_3Ge thin films (Cadieu & Weaver, 1973). Since then, much effort has been devoted to superconductor research in many laboratories around the world, and hundreds of new superconductors with different structure types in different chemical systems have been successfully prepared. Cuprate high-temperature superconductors (HTSCs) are among the most interesting systems. A T_c of 93 K was found in the $YBa_2Cu_3O_{7-x}$ system (Wu *et al.*, 1987) and a T_c of 120 K was measured for the compound $Tl_2CaBa_2Cu_2O_{8+\delta}$ (Gao *et al.*, 1988). The highest T_c, 164 K, was observed in the $HgBa_2Ca_2Cu_3O_{8+x}$ system under pressure at 31 GPa (Gao *et al.*, 1994). Of the many non-Cu-containing superconducting systems, the Fe-based family has attracted recent interest for its high-T_c properties. In this family, the compound $NdFeAsO_{1-x}F_x$ has T_c = 55 K (Ren, Yang *et al.*, 2008). Selected superconducting systems and their years of discovery are given in Table 7.13.1. A few typical structure types are shown in Fig. 7.13.2.

The property of superconductivity relates closely to the structure type, chemical composition, the distribution of the atoms and/or ions in a material, and the temperature and pressure. Superconductivity can be shown by elements, alloys, intermetallics and chemical compounds with more complex compositions, and can be found in stoichiometric or nonstoichiometric materials.

Elements, alloys and intermetallics. Elemental superconductors can show type-I or type-II behaviour. The majority of the superconducting elements are members of the transition-metal series with a T_c as high as 9.3 K in Nb. Combinations of the transition elements with a number of other elements lead to the formation of superconducting alloys (with random atomic ordering) and intermetallic compounds [ordered crystallographically, such as Nb_3Ge (Fig. 7.13.2*a*) and MgB_2 (Fig. 7.13.2*c*)]. Fullerides (Gunnarsson, 1997; Buntar & Weber, 1996) are compounds with the general formula A_nC_{60} [the structure of an example with $n = 3$ is shown in Fig. 7.13.2(*b*)] and can become superconductors at high temperatures. The present record under pressure is held by Cs_3C_{60} with T_c = 40 K.

Transition-metal oxides with perovskite-like and layered structures (Figs. 7.13.2*e*, *f* and *g*). Oxide materials are strong type-II superconductors. Most superconducting oxides contain a transition metal. T_c's for transition-metal oxides range from low (T_c = 0.7 K for $SrTiO_{3-x}$) to above liquid-nitrogen temperature, such as for $HgBa_2Ca_2Cu_3O_{8+x}$, which has a T_c of 133 K (Antipov *et al.*, 1993). Cuprate HTSCs have played a central role in the scientific and technological development of superconductors. For other

Definitions of superconductivity. (*a*) A superconductor shows zero resistance to a flow of current below T_c. The magnetic field *versus* temperature diagram for (*b*) a typical elemental type-I superconductor and (*c*) for a type-II superconductor. In regions SC in (*b*) and SC1 in (*c*) the material shows perfect diamagnetic behaviour and in the SC2 region the materials shows imperfect diamagnetic behaviour.

oxides, a T_c as high as 30 K has been found in $Ba_{1-x}K_xBiO_3$ (Cava *et al.*, 1988). A large proportion of high-T_c superconductors are copper oxides with layer-stacking structures that contain Cu in a mixed-valence state.

Fe-based systems and borocarbides with the $ThCr_2Si_2$-type structure. These constitute another important family of superconducting systems. T_c has been observed to be as high as 55 K in the $RFeAsO_{1-x}F_x$ (Fig. 7.13.2*i*) system (Ren & Zhao, 2009). These materials can be considered as interstitial derivatives of the $ThCr_2Si_2$-type structure in which the transition metal T is surrounded by four Q ions or atoms, forming conducting blocks of TQ_4 edge-sharing tetrahedra that alternate with charge-reservoir layers (metal layers or oxide blocks). The Q ions are elements belonging to Groups 14, 15 or 16. There are two major types of materials: (i) the nonstoichiometric Fe-based pnictides or chalcogenides; and (ii) the stoichiometric intermetallics and borocarbides [such as YPd_2B_2C: see Fig. 7.13.2(*h*)] with a T_c as high as 23 K (Cava, Takagi, Batlogg *et al.*, 1994).

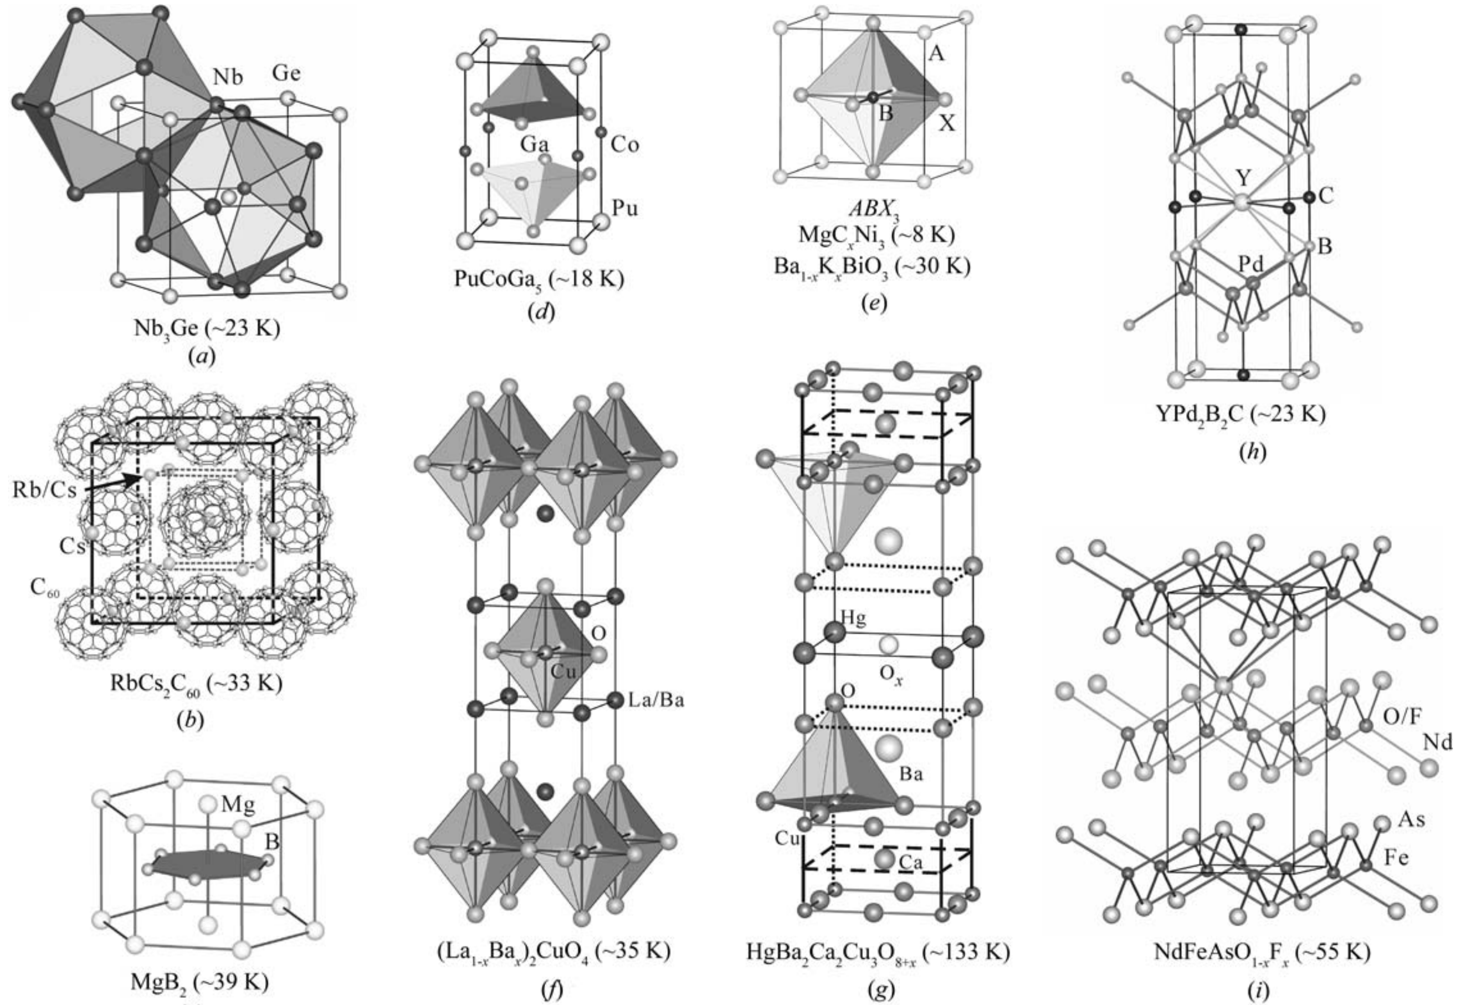

Figure 7.13.2

Typical structures for higher-T_c superconducting compounds shown in Table 7.13.1. The highest T_c reported in each system is given. (*a*) Nb_3Ge intermetallic; (*b*) $RbCs_2C_{60}$ 'buckyball'; (*c*) MgB_2 diboride; (*d*) the heavy-fermion superconductor $PuCoGa_5$; (*e*) intermetallic MgC_xNi_3 antiperovskite and $Ba_{1-x}K_xBiO_3$ perovskite; (*f*) $(La_{1-x}Ba_x)_2CuO_4$ perovskite-like layered cuprate; (*g*) $HgBa_2Ca_2Cu_3O_{8+x}$ layered copper oxide; (*h*) YPd_2B_2C borocarbide; (*i*) $NdFeAsO_{1-x}F_x$ iron-based layered compounds.

Heavy-fermion and magnetic superconductors. Heavy-fermion (HF) systems are stoichiometric lanthanide or actinide compounds whose qualitative low-temperature behaviour in the normal state closely parallels that of simple metals. The HF superconductors $PuCoGa_5$ (Fig. 7.13.2*d*) (Sarrao *et al.*, 2002) and $CeCu_2Si_2$ (Steglich *et al.*, 1979) contain disordered *f*-electron magnetic moments on Pu and Ce. At low temperature, a strong correlation between the *f*-electrons and conduction electrons develops, which results in effective masses for the conduction electrons that are one or two orders of magnitude larger than the free electron mass, and strong antiferromagnetic (AFM) spin correlations exist between the *f*-electron moments themselves. These correlations may condense into an ordered AFM state of heavy electrons, or lead to heavy-electron superconductivity, or lead to the coexistence of an AFM state and superconductivity under certain conditions. In a magnetic superconductor, the system contains transition-metal or rare-earth magnetic ions. The magnetic ions influence the superconducting properties more significantly than non-magnetic impurities. Long-range magnetic order may coexist with superconductivity; this has been found in cuprates (Lynn & Skanthakumar, 2001), borocarbides (Lynn *et al.*, 1997; Müller & Narozhnyi, 2001; Nagamatsu *et al.*, 2001; Nagarajan, 1997) and HF and Fe-based superconductors (Lynn & Dai, 2009; Lumsden & Christianson, 2010).

7.13.2. Advantages of structure analysis from powder diffraction

Obtaining structural information is one of the central issues in research on superconductivity. In general, X-ray and neutron powder diffraction (hereafter XPD and NPD, respectively) are the most convenient and powerful techniques for obtaining such information directly, and they are widely used in laboratories around the world. There are many important reasons for preferring powder over single-crystal analysis:

(*a*) In many systems it is almost impossible to grow single crystals of specified phases or compositions. Moreover, expensive equipment and a great deal of experience at crystal growing are needed.

(*b*) Superconducting compounds have small unit cells and high structural symmetry and, therefore, high-quality XPD and NPD data can often be obtained conveniently under different conditions. Rietveld structure refinement (Rietveld, 1969) and related methods of data analysis allow us to determine and to refine the crystal and magnetic structures, to detect phase transformations, and to identify the phases in polycrystalline samples.

(*c*) The study of powder samples is also convenient when special environmental conditions are required (low and high temperatures, high pressure *etc.*) and when diffraction, magnetization and resistivity measurements have to be done on the sample under such special conditions.

(*d*) For twinned systems where the structural distortions from higher-symmetry parent structures are not large, powder diffraction can allow for more unambiguous determination of the structures of the phase, because in single-crystal diffraction there may not be sufficient resolution to isolate the diffraction from a single twin.

The Rietveld method is a whole-pattern least-squares fitting method for extracting detailed crystal and magnetic structural information from XPD and NPD data. A detailed description was given by Young (1993); see also Chapter 4.7. The method uses directly the profile intensities obtained from measurements of the powder-diffraction pattern using either a fixed angle (energy-dispersive) or a fixed wavelength (angle-dispersive). Nuclear as well as magnetic structures can be refined, and a large number of successful refinements by this method have been reported. As an example, Von Dreele & Cheetham (1974) reported a refinement of 41 structure parameters, using NPD data, for $Ti_2Nb_{10}O_{29}$, which has the space group *Amma* and a unit-cell volume of 2178 Å^3. Experimentally, the Rietveld method is one of the most useful techniques for structural studies of superconductors.

7.13.2.1. *Comparison of XPD and NPD*

A good powder-diffraction pattern for structure determination and refinement using the Rietveld method should have a considerable number of independent Bragg reflections with strong intensities, precise peak positions with good resolution, and only small systematic errors.

The positions of the Bragg reflections are given by

$$2d_{hkl}\sin\theta = n\lambda, \tag{7.13.1}$$

where λ is the incident-beam wavelength, d are the distances between successive *hkl* planes and θ are the Bragg angles of reflections, and the intensitities I are proportional to the square of the structure-factor amplitudes $|F_{hkl}|$:

$$I \propto |F_{hkl}|^2. \tag{7.13.2}$$

For X-rays

$$F^2_{hkl} = \left|\sum f_j \exp(2\pi i)(hx/a_0 + ky/b_0 + lz/c_0)\right|^2 \exp(-2W), \tag{7.13.3}$$

where f_j is the atomic scattering factor of atom j, a_0, b_0 and c_0 are the unit-cell parameters and x, y, z are the fractional atomic coordinates.

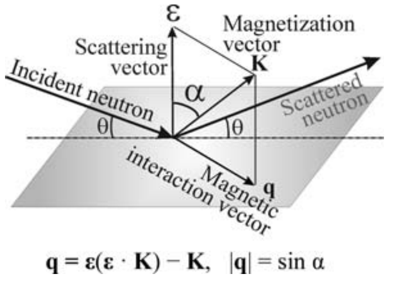

Figure 7.13.3
Definition of the vectors relevant in the evaluation of the magnetic structure factor. $\boldsymbol{\varepsilon}$ and $\mathbf{K}$ are unit vectors in the directions of the scattering and magnetic moment, respectively. The magnetic interaction vector $\mathbf{q}$ is always perpendicular to the scattering vector.

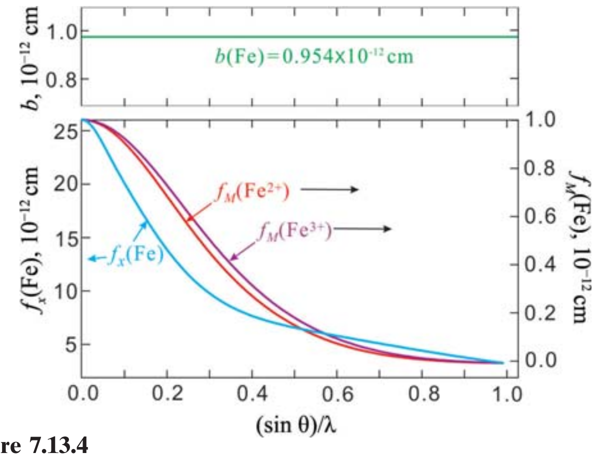

Figure 7.13.4
Angular dependence of the atomic scattering amplitudes of iron for X-rays [f_x(Fe)] and neutrons [b(Fe)], and of the magnetic form factors for Fe^{2+} [f_M(Fe^{2+})] and Fe^{3+} [f_M(Fe^{3+})]. The curves were calculated using the program *GSAS* (Larson & Von Dreele, 2004).

For neutrons

$$F^2_{hkl} = \left|\sum b_j \exp(2\pi i)(hx/a_0 + ky/b_0 + lz/c_0)\right|^2 \exp(-2W), \tag{7.13.4}$$

where b_j is the neutron scattering length for atom j.

For magnetic scattering

$$F^2_{hkl} = \left|\sum \mathbf{q}_j f_{Mj} \exp(2\pi i)(hx/a_0 + ky/b_0 + lz/c_0)\right|^2 \exp(-2W), \tag{7.13.5}$$

where $\mathbf{q}_j$ and f_{Mj} are the magnetic interaction vector and the magnetic form factor for atom j, respectively. $W = B(\sin^2\theta/\lambda^2)$ where B is the displacement parameter (Waller, 1923, 1926, 1927, 1928). The definition of $\mathbf{q}$ is indicated in Fig. 7.13.3.

In all the preceding formulas, the sums are over all the atoms in the unit cell of the structure. Fig. 7.13.4 is an example of the angular dependence of the atomic scattering amplitudes and magnetic form factors. The absolute values of the atomic scattering amplitudes for X-rays in the low-angle range of 2θ are considerably greater than those of neutrons, and this is reflected in the structure factors and in the magnitudes of the corresponding intensities of the Bragg peaks. However, the fact that the values of the atomic scattering amplitudes for neutrons remain constant as 2θ changes makes the neutron-diffraction intensities in the high-angle range comparable with those of low-angle reflections. This is an advantage when accurate measurements of displacement parameters are necessary, and to reduce correlation between displacement and occupancy parameters. The magnetic form factor for neutron diffraction is an angle-dependent parameter: its amplitude decreases with increasing θ. Most of the magnetic diffraction intensity, therefore, is found in the low-angle part of a diffraction pattern.

Another vitally important application of neutron diffraction is to study the magnetic structures and properties of materials. As shown in Fig. 7.13.3, the magnetic interaction vector is defined by

$$\mathbf{q} = \boldsymbol{\varepsilon}(\boldsymbol{\varepsilon} \cdot \mathbf{K}) - \mathbf{K}, \tag{7.13.6}$$

where the scattering factor $\boldsymbol{\varepsilon}$ is a unit vector in a direction perpendicular to the effective reflecting plane and the magnetization vector $\mathbf{K}$ is a unit vector in the direction of the atomic magnetic moment. Here we have $|\mathbf{q}| = \sin\alpha$, *i.e.* the magnetic structure factor F_{hkl} will be zero when $\boldsymbol{\varepsilon}_{hkl}$ is parallel to $\mathbf{K}$, which

Schematic representation of the choice of radiation recommended for powder-diffraction experiments to obtain different structural information in research on superconductivity.

means it is possible to find the direction of an ordered magnetic moment from NPD data.

7.13.2.2. *Choice of radiation*

In principle, the appropriate choice of the radiation used for powder-diffraction experiments depends on whether it will provide the required information on the structure. The examples in Table 7.13.1 show that superconductors and related compounds have a great variety of chemical compositions and structure types. This can make choosing the optimal technique rather complicated. For example, in many circumstances a compound consists of heavy and light elements or atoms with similar atomic numbers at the same site in a structure. In such cases, the use of X-ray diffraction may not be appropriate, since the light atoms cannot be easily located, and the technique is not the best for distinguishing atoms with similar atomic numbers. On the other hand, XPD offers the advantage of a resolution better than that achievable with even the best neutron diffractometer, and therefore can better detect the splitting of diffraction peaks that could indicate a phase transition. NPD is not able to distinguish between elements with similar neutron-scattering amplitudes located at the same site in a structure; however, it is essential for the study of magnetic materials. Choosing the most appropriate radiation for a powder-diffraction experiment in any particular case can be facilitated by analysis of Fig. 7.13.5, a schematic representation of the usefulness of XPD and NPD.

7.13.3. Analysis of the chemical and structural features of nonstoichiometric superconductors

Determining the chemical and structural features of a superconductor will require choosing the radiation (often more than one type), designing the data-collection conditions and obtaining good powder-diffraction data in order to obtain useful and reliable information for each particular case. Many superconductors are nonstoichiometric intermetallics, solid solutions or complex compounds. A common feature of these superconductors is that the superconducting property is a function of composition. For those superconductors, structure refinement using powder-diffraction data is used to determine the chemical formula and to study the relationships between T_c and composition. The intermetallic system $Nb_{3+x}Ge_{1-x}$ has its highest T_c of 23 K at $x = 0$. In the $BaPb_{1-x}Bi_xO_3$ solid-solution system, superconductivity was found in the composition range $0.05 < x < 0.3$ (Sleight *et al.*, 1975). The compound $HgBa_2Ca_2Cu_3O_{8+x}$ has the highest T_c of 133 K at the optimal composition $x = 0.42$. Moreover, for a compound having different structural modifications the powder-diffraction technique can be used to identify the structure of the superconducting phase. For example, the compound $La_{1.85}Ba_{0.15}CuO_4$ was found to have several modifications with different space groups, and their superconducting properties were studied (Axe *et al.*, 1989).

7.13.3.1. *Charge transfer and valence-state manipulation*

Charge transfer. It has been proved that charge transfer in high-T_c cuprate and Fe-based superconductors, and in many other nonstoichiometric superconducting systems plays a very important role in their superconducting properties. A schematic view in Fig. 7.13.6 shows a sketch of the charge transfer between the conducting and the charge-reservoir layers. The electron transfer changes the charge distribution in the structure and affects the superconductivity.

In general, it is believed that the CuO_2 plane is the conducting layer responsible for the superconductivity in copper-oxide superconductors. In the Fe-based and related superconductors having the $ThCr_2Si_2$-type structure, the conducting layer is considered to be the $T_{1-x}Q_4$ edge-sharing tetrahedral blocks that form a two-dimensional network (T is transition metal and Q is an element from Groups 15, 16 or 17). The atom T in the conducting layer may have a mixed valence state and may form covalent, semi-covalent or ionic bonds with the Q atoms. The concentration of charge carriers in the conducting layers varies when the formal charge of the transition metal T is varied. Near the conducting layer the reservoir layer acts as a charge donor to provide charge to the conducting layer. Electron transfer from the conducting layer to the charge-reservoir layer is known as 'hole doping' (on the right in Fig. 7.13.6) and moving electrons from the charge-reservoir layer to the conducting layer (on the left of Fig. 7.13.6) is known as 'electron doping'. The hole-type or electron-type charge carrier concentrations in the conducting layer are strongly related to the superconductivity. Typically, the cations in the conducting layers are transition metals that can exist in different valence states, and the cations in the

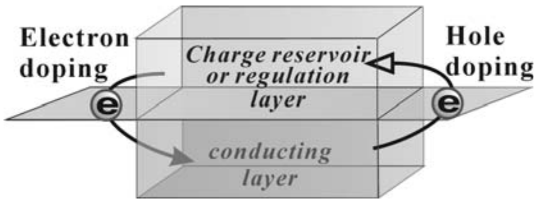

Figure 7.13.6
Schematic view of charge transfer between the conduction layer and the charge-reservoir layer in superconducting and related compounds. Electron transfer from the conducting layer to the charge-reservoir layer is known as 'hole doping' and movement of electrons from the charge-reservoir layer to the conducting layer is known as 'electron doping'.

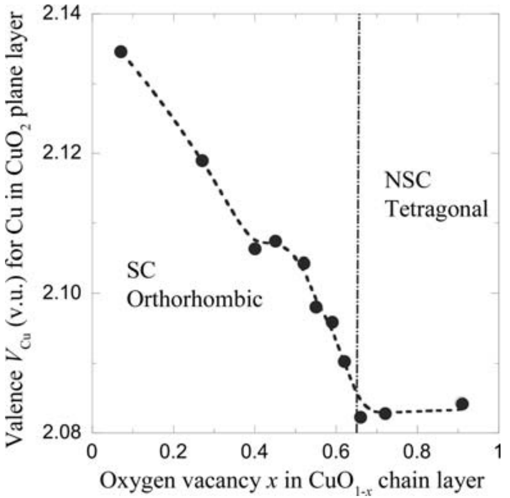

Figure 7.13.7
Calculated atomic valence for Cu in the CuO_2 plane layer *versus* oxygen content in the chain layer of $YBa_2Cu_3O_{7-x}$. The bond-distance data used in the calculation are based on the structure information reported by Jorgensen *et al.* (1990).

charge-reservoir layers are rare-earth elements, alkali metals and alkaline-earth metals that have a stable valence state.

The charge transformation can be achieved by adjusting the chemical composition through substitution, doping and vacancy introduction, and can be found indirectly by analysing the valence using bond distances.

Bond-valence analysis can be used to find evidence of charge transfer. In inorganic compounds, the valence of each atom is distributed between the bonds that it forms, and it is always possible to associate a valence with each bond in such a way that the sum of the bond valences around each atom is equal to its atomic valence (Brown, 1976, 2002; Brown & Altermatt, 1985). The valence for each bond can be calculated using

$$v_{ij} = \exp[(r_0 - r_{ij})/b], \qquad (7.13.7)$$

where r_0 is the bond-valence parameter, which is the hypothetical length of a bond of unit valence, v_{ij} is the bond valence and r_{ij} is the experimental (Brown & Altermatt, 1985) distance between atoms i and j; the constant b is 0.37. The total valence V_i for an atom i is the sum (over j) of the surrounding bond valences:

$$V_i = \sum_{j=1}^{j=n} v_j, \qquad (7.13.8)$$

where n is the number of bonds.

Example. It is very well known that the superconducting properties are strongly related to the oxygen content in the $YBa_2Cu_3O_{7-x}$ system. Jorgensen *et al.* (1990) reported the structure–property relationship for different levels of oxygen deficiency in this system with very detailed structure information obtained using NPD data. Fig. 7.13.7 shows the valence calculated using equation (7.13.8) for Cu in the conducting layer (CuO_2) as a function of the oxygen content x in the (CuO_x) layer. The behaviour is very similar to the variations of T_c as the oxygen vacancy x increases, with two plateaus being observed. In the range $0 < x < 0.35$, T_c decreases from 94 to 56 K, where the calculated valence for Cu, V_{Cu}, deceases from 2.135 to 2.108 valence units (v.u.). T_c was found to be constant with a value near 56 K for $0.35 < x < 0.45$, where a corresponding plateau is observed near V_{Cu} = 2.108. Then V_{Cu} drops rapidly to about 2.082 v.u. where T_c decreases from 56 K to zero near x = 0.65.

Cation substitution in superconducting oxides. After high-temperature superconductivity was discovered in the $(La,Ba)_2CuO_4$ system by Bednorz & Muller (1986), Takagi *et al.* (1987) confirmed that the superconducting phase $(La_{0.925}Ba_{0.075})_2CuO_4$ has the K_2NiF_4-type tetragonal structure with space group *I*4/*mmm* (No. 139) at high temperature (Fig. 7.13.8*a*), with atom positions ($La_{0.925}Ba_{0.075}$): 4*e* (0, 0, z); Cu: 2*a* (0, 0, 0); O1: 4*c* (0, $\frac{1}{2}$, 0) and O2: 4*e* (0, 0, z). There have been many studies concerning the role of cation substitution, oxygen vacancy and structural phase transitions in the high-T_c

Schematic layer-stacking structures of (*a*) $(R_{1-x}M_x)_2CuO_4$ and (*b*) $HgBa_2CuO_{4+x}$ indicating the charge transfer between the reservoir and superconducting layers.

$(R_{1-x-y}M_xR'_y)_2CuO_{4-\delta}$ system, where R is a trivalent rare earth (La^{3+}, Nd^{3+}, Pr^{3+} . . .) and R' is tetravalent Ce^{4+}; M can be Ba^{2+} or Sr^{2+}.

The parent compounds La_2CuO_4 and Nd_2CuO_4 are semiconductors, and have valences of 3+, 2+ and 2− for the La/Nd, Cu and O ions, respectively. Superconductivity in these materials is induced by either holes or electrons in the charge-reservoir layer. This is accomplished by partial substitution of La^{3+} or Nd^{3+} at the 4e site with atoms of lower or higher valences, thus making the average formal valence of the site smaller or larger than 3+. Consequently, the formal Cu valence will be larger (hole doping) or smaller (electron doping) than 2+, respectively. More specifically, in the hole-doping case, substitution of Ba^{2+} for La^{3+} will cause an electron transfer from the adjacent CuO_2 conducting layers to the charge-reservoir layers, *i.e.* the oxidation state of copper will assume a value between 2+ and 3+. In fact, the compound $La_{1.85}Ba_{0.15}CuO_4$ becomes a superconductor below $T_c \simeq 30$ K by changing the formal valence of copper to 2.15+ instead of 2+. In the electron-doping case of $(Nd_{1-x}Ce_x)_2CuO_{4-\delta}$, the partial substitution of Ce^{4+} for Nd^{3+} and/or the presence of oxygen defects will generate an electron transfer from the reservoir to the conducting layers with consequent reduction of the copper formal valence from 2+ to between 2+ and 1+. Thus the superconducting compound $Nd_{1.845}Ce_{0.155}CuO_{3.93}$ (Izumi *et al.*, 1989) has the formal copper valence reduced to $Cu^{1.71+}$.

(*a*) Schematic view of electron transfer in Fe-based superconducting and related compounds. It is believed that the block of edge-sharing TQ_4 tetrahedra contributes to the superconductivity. (*b*) $AE_{1-x}A_xFe_2Pn_2$ (Rotter *et al.*, 2008) and $A_yFe_{2-x}Ch_2$, where AE are alkaline-earth metals and A are alkali metals; (*c*) RFeAs$O_{1-x}F_x$; and (*d*) phases, Sr_2MFePnO_3, where M = Sc, Ti, V.

Remarks. Choosing the proper radiation is key for determining the superconducting composition and the doping state (electron or hole doping). In the $(La_{1-x}Ba_x)_2CuO_{4-y}$ case, it is impossible to refine the ratio of La:Ba using XPD data because Ba and La have a similar atomic numbers ($Z_{Ba} = 56$ and $Z_{La} = 57$). However, using NPD data La and Ba can be distinguished well by Rietveld refinement because the neutron scattering amplitude of La ($0.827\ cm^{-12}$) is 57% larger than that of Ba ($0.525\ cm^{-12}$). However, the situation is more complex for the $(Nd_{1-x-y}Sr_xCe_y)_2CuO_{4+\delta}$ system, where three different elements occupy the same crystallographic site. The formal valence of copper can be larger or smaller than 2+, depending on the values of x, y and δ. Combined refinements using XPD and NPD data were able to determine the values x, y and δ as follows:

(i) Considering that Nd ($Z_{Nd} = 58$) and Ce ($Z_{Ce} = 60$) have similar atomic numbers Z, but quite different from that of Sr ($Z_{Sr} = 38$), and the amount of Ce in the compound is much less than the amount of Nd, the formula can be simplified to $[(Nd/Ce)_{1-x}Sr_x]_2CuO_{4-\delta}$ and x can be obtained from refinement using XPD data.

(ii) Fixing the x value obtained from step (i), the y value can be obtained from refinement using NPD data, where the difference in the neutron scattering amplitude between Ce ($0.484\ cm^{-12}$) and Nd ($0.769\ cm^{-12}$) is large.

(iii) The NPD data can be used to refine the oxygen vacancy δ, because O has a comparable neutron scattering amplitude ($0.525\ cm^{-12}$) to that of the cations.

Oxygen stoichiometry in superconducting cuprates and oxides. It is accepted that the oxygen stoichiometry dramatically affects the properties of HTSCs in most non-stoichiometric superconducting cuprates and oxides. In the $HgBa_2Ca_{n-1}Cu_nO_{2(n+1)+x}$ system, the parent compounds ($x = 0$) are all non-superconductors. When $x = 0.06$, the $n = 1$ compound $HgBa_2CuO_{4+x}$ has a T_c of 94 K (Fig. 7.13.8*b*) (Putilin *et al.*, 1993). The non-superconducting parent compound $HgBa_2CuO_4$ ($x = 0$) has Hg^{2+}, Ba^{2+}, Cu^{2+} and O^{2-}. By adding oxygen atoms to the HgO_x charge-reservoir layer, the formal copper valence is increased from Cu^{2+} to $Cu^{(2+\delta)+}$ and the compound becomes a hole-doped superconductor. In this system T_c has been found to be as high as 133 K (Antipov *et al.*, 1993; Chmaissem *et al.*, 1993) for the $n = 3$ compound $HgBa_2Ca_2Cu_3O_{8+x}$ with $x = 0.42$, *i.e.* the additional 0.42 oxygen atoms increase the formal copper valence from Cu^{2+} to $Cu^{2.26+}$.

Remarks: Compared with the metal atoms in these nonstoichiometric superconducting cuprates and oxides, oxygen is a light element and has a smaller X-ray scattering amplitude. Therefore, NPD data were needed to refine the oxygen occupancy, since the neutron scattering amplitude of O is similar to those of the metal atoms.

Cation and anion substitution in Fe-based superconductors. The Fe-based pnictide (Pn) and chalcogenide (Ch) families have Fe-containing layers in which the Fe atoms are coordinated by four pnictogen or chalcogen (Q) ions forming a block of FeQ_4 edge-sharing tetrahedra. The first superconductor observed in this system was LaFePO ($T_c = 5$ K), found by Kamihara *et al.* (2006). On replacing P by As, T_c increases to 26 K in the $LaFeAs(O_{1-x}F_x)$ system (Kamihara *et al.*, 2008). Soon after, a series of related superconductors were reported in the RFeAs$(O_{1-x}F_x)$ and RFeAsO_x systems with a maximum T_c of up to 55 K (Ren, Yang *et al.*, 2008; Ren, Che *et al.*, 2008).

Fe–Pn(Ch) compounds have high chemical and structural flexibility for a large variety of constituent elements. Like the high-T_c cuprates, where Cu has a mixed valence in the conducting

References: Cava (2000); Park & Snyder (1995); Hauck & Mika (1998); Tokura & Arima (1990); Parkin *et al.* (1988).

layers, the formal valence for iron can be adjusted from Fe^{2+} to $Fe^{(2\pm\delta)+}$ when electrons are transferred between the conducting and charge-reservoir layers, as shown in Fig. 7.13.9(*a*). Changing the valence state of Fe can be achieved by cation or anion doping. The layer or block between the blocks of $FeAs(Se)_4$ edge-sharing tetrahedra is the charge-reservoir unit: it can be a simple layer (Fig. 7.13.9*b*) or complex blocks (Figs. 7.13.9*c*, 7.13.9*d*). For the $Ba_{1-x}K_xFe_2As_2$ system shown in Fig. 7.13.9(*b*), the parent compound $BaFe_2As_2$ ($x = 0$) contains Ba^{2+}, Fe^{2+} and As^{3-} and is not a superconductor. Partial substitution of Ba^{2+} with the lower-valence cation K^{1+} will make the average formal valence for Fe larger than 2+ and the compound becomes a superconductor. In the $RFeAs(O_{1-x}F_x)$ system (Fig. 7.13.9*c*), the superconductivity can be introduced by electron doping when the formal valence for Fe is adjusted to be smaller than 2+ through partial replacement of F^{1-} with O^{2-}.

Remarks. As Ba has a higher atomic number than K but the neutron scattering amplitudes for Ba and K are very similar, XPD data should be better than NPD data for determining the K content in $(Ba_{1-x}K_x)Fe_2As_2$ compounds. On the other hand, neither XPD nor NPD data can be used to obtain the F content when replacing O by F in the $RFeAs(O_{1-x}F_x)$ system because of the small difference in both the numbers of electrons and the neutron scattering amplitudes for O and F.

7.13.3.2. *Modelling of layer structures*

Stacked layers are widely found in the structures of the cuprate superconductors and are used to explain the charge transfer. The structural features of the layered superconducting copper oxides and of related materials have been described in many reviews (Sleight, 1988; Tokura & Arima, 1990; Park & Snyder, 1995; Raveau *et al.*, 2013). Selected high-T_c copper-oxide systems with the stacking described below are shown in Table 7.13.2. These structures are formed by stacking layers of the conducting and intermediate layers. The intermediate layers can be charge-reservoir or 'regulation' layers. In the structures of $(R_{1-x}M_x)_2CuO_4$ and $HgBa_2CuO_{4+x}$, illustrated in Fig. 7.13.8, the CuO_2 plane is the conducting layer, and $(R_{1-x}M_x)O_y$ and HgO_x are the charge-reservoir layers. The BaO layer in $HgBa_2CuO_{4+x}$ is a regulation layer where the occupancies and valences of Ba and O remain unchanged. The structure is constructed by the following layer-stacking sequences:

$(R_{1-x}M_x)_2CuO_4$: $\{CuO_2\}_O$ $[R_{1-x}M_xO]_C$ $[R_{1-x}M_xO]_O$ $\{CuO_2\}_C$ $[R_{1-x}M_xO]_O$ $[R_{1-x}M_xO]_C$ $\{CuO_2\}_O \ldots$

$HgBa_2CuO_{4+x}$: $\{CuO_2\}_O$ $(BaO)_C$ $[HgO_x]_O$ $(BaO)_C$ $\{CuO_2\}_O$.

The chemical symbols enclosed in braces, square brackets and parentheses express the actual compositions of the conducting, charge-reservoir and regulation layers, respectively, and the subscripts *O* and *C* indicate whether the cation is located at the origin or at the centre, respectively, of the net of the layer. In $(R_{1-x}M_x)_2CuO_4$, the conducting CuO_2 layers sandwich the $R_{1-x}M_xO$ charge-reservoir layers in alternating stacking along the *c* axis. A few typical layer structures are illustrated in Fig. 7.13.10. Fig. 7.13.11 shows the stacking structure along the *c* axis of the $HgBa_2Ca_{n-1}Cu_nO_{2(n+1)+x}$ ($n = 1, 2, 3, 4, 5, 6$) series of superconductors. The structures can be constructed in the following way, where the charge-reservoir unit is shown in bold:

$\ldots\{CuO_2\}_O\,(Ca)_C\,\{CuO_2\}_O\,\mathbf{(BaO)_{\mathit{C}}\,[HgO_{\mathit{x}}]_{\mathit{O}}\,(BaO)_{\mathit{C}}}\,\{CuO_2\}_O\,(Ca)_C\,\{CuO_2\}_O\ldots$

Using the charge-reservoir unit as a centre, the CuO_2 and the Ca layers are stacked alternately along the *c* axis. The Ca layers

do not act as donors of charge carriers and only play the role of regulation layers for the geometric requirements of the structure. T_c depends on the oxygen content in the HgO_x charge-reservoir layer, and is strongly correlated with the number of $\mathrm{CuO_2}$ layers.

7.13.3.3. *Structural transformations*

Above T_c, a superconductor may be an electron insulator, a semiconductor or a metallic conductor. Changes in the electron-transport behaviour are in some cases accompanied by structural modifications due to structure distortions, chemical order–disorder and/or variations in composition. The different structures may belong to different crystal systems, or belong to the same crystal system but have different space groups; this can be determined by analysing the powder-diffraction pattern. Fig. 7.13.12 shows some examples of possible diffraction-peak positions calculated by considering only the primitive lattice. [Symmetry relations between space groups during structural distortions are discussed in *International Tables for Crystallography*, Volume A1 (2011).]

For data collection, the high resolution available for XPD (especially at a synchrotron) is beneficial for detecting the peak splittings that result from a small lattice distortion, and NPD has an advantage in measuring superstructure peaks where intensities come from small shifts of light elements.

Perovskite-like structure distortions. Superconductivity has been found in many compounds with perovskite-like structures. An ideal perovskite has the chemical formula ABX_3 with cubic $Pm\bar{3}m$ symmetry and with atomic positions A: 1a (0, 0, 0), B: 1b ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$) and X: 3c ($\frac{1}{2}$, $\frac{1}{2}$, 0) [see Fig. 7.13.2(*e*)]. In practice it has been found that the perovskite structure exists if $0.75 \le p \le 1.0$, where

$$p = (r_A + r_X)/[2^{1/2}(r_B + r_X)];$$

p is Goldschmidt's tolerance factor (Goldschmidt, 1926) and r_A, r_B and r_X are the ionic radii (Shannon, 1976) of A, B and X, respectively. The A and B ions are located at the corners and at the centre of the cubic unit cell, respectively. The ions X are located at the centre of the six faces of the cubic cell and form an octahedron around the B cation. Each octahedron shares corners with the nearest neighbours. The distortion of the octahedra and/or their tilting results in different modifications of the ideal structure. Fig. 7.13.13 shows an example in which the octahedron at the centre and the four surrounding octahedra are rotated in opposite directions around the cubic c axis. Such rotations are responsible for a lowering of the symmetry from cubic to trigonal, tetragonal, orthorhombic or monoclinic (Glazer, 1972, 1975). The distortions can be temperature and/or composition dependent, as happens in the perovskite-like system $\mathrm{(La,Ba)_2CuO_4}$ (Axe *et al.*, 1989) as well as in $\mathrm{BaBi_{1-x}Pb_xO_3}$ (Cox & Sleight, 1976; Marx *et al.*, 1992).

Tetrahedral distortions. A structural transition due to polyhedral distortion is also present in Fe-based superconductors. As an example, the parent compound LaFeAsO of the $\mathrm{LaFeAsO_{1-x}F_x}$ superconductor has a structure with $P4/nmm$ symmetry and lattice parameters a_t = 4.03007 (9) Å and c_t = 8.7368 (2) Å at 175 K (Nomura *et al.*, 2008). The polyhedral distortion breaks the tetragonal symmetry below 155 K and the material becomes orthorhombic with $Cmma$ symmetry. The axes transformation from the tetragonal to the orthorhombic phase is $(a_o\ b_o\ c_o) = (110/\bar{1}10/001)(a_t\ b_t\ c_t)$, and the relation between the lattice parameters of the two phases is $a_o \simeq b_o \simeq 2^{1/2}a_t$ and $c_o \simeq c_t$. In this case, peak splitting and superlattice peaks will be present in the powder pattern.

Stoichiometry dependence and vacancy ordering. Order–disorder transitions can be induced by external forces (temperature and pressure) and/or internal forces (chemical composition). Chemical order–disorder is present in both the cuprate and Fe-based high-T_c superconducting families, as observed in the $\mathrm{YBa_2Cu_3O_{7-x}}$ and $\mathrm{K_xFe_{2-y}Se_2}$ systems.

The crystal structure and phase transition of $\mathrm{YBa_2Cu_3O_{7-x}}$ have been studied carefully with the Rietveld method, using both XPD and NPD data (Cava *et al.*, 1987; Jorgensen *et al.*, 1987, 1990). The results revealed the presence of oxygen vacancies in the $\mathrm{CuO_{1-x}}$ charge layer (see Fig. 7.13.14*a*) and the structure undergoes an orthorhombic $Pmmm$ to a tetragonal $P4/mmm$

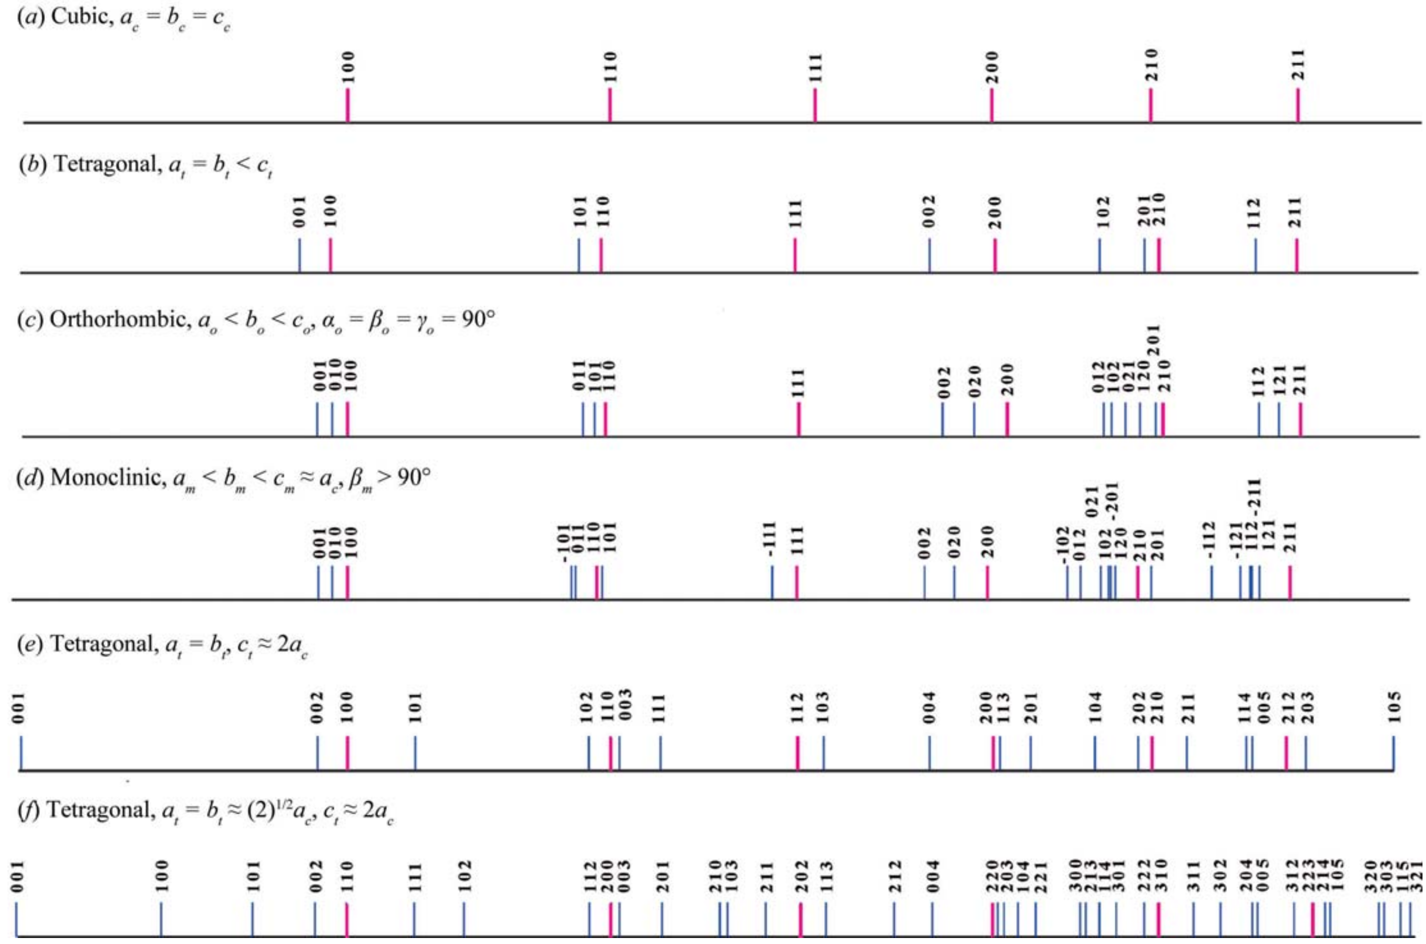

Figure 7.13.12
Schematic plot of the possible diffraction peaks with consideration of the primitive lattice only. The thick red lines are the reflections corresponding to a cubic lattice, and the thin blue lines are the reflections due to the peak splitting or the superlattice peaks. (*a*) Reflections from a simple cubic lattice; (*b*), (*c*) and (*d*) reflections from tetragonal, orthorhombic and monoclinic lattices, respectively. As a result of the lattice distortion, a cubic peak may be split into two or more peaks; in (*e*) and (*f*) reflections show the presence of peak splitting and also superlattice peaks (such as the peaks for *hkl* with *l* = odd) from the superlattice.

transition. The transition is induced by a change in the oxygen stoichiometry and is a function of temperature. The orthorhombic phase exists over the range $0 \leq x < 0.65$, with the oxygen vacancies along the *a* axis. The remaining oxygen atoms form chains along the *b* axis within square-planar CuO_4 motifs, coordinated in the *b*–*c* plane (Fig. 7.13.14*b*). The vacancies are disordered in the tetragonal phase ($x > {\sim}0.65$), thus destroying the Cu—O chains of the orthorhombic modification (Fig. 7.13.14*c*).

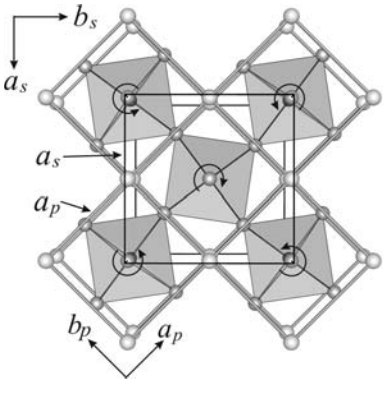

Figure 7.13.13
A structural transformation induced by a rotation of the octahedra in the perovskite structure. A projection along the *c* direction, showing that the rotation of the corner-shared octahedra is responsible for the symmetry change and for the formation of a superstructure in which $a_s = b_s = 2^{1/2}a_p$ and $c_s = c_p$, where a_p (= b_p = c_p) is the lattice parameter for the cubic perovskite and a_s, b_s and c_s are the parameters of the superlattice.

Structural transitions are observed due to the iron-vacancy ordering in the $A_xFe_{2-y}Se_2$ system. Guo *et al.* (2010) first reported a T_c of 31 K in $K_xFe_{2-y}Se_2$. Different iron-vacancy ordering models have been reported in compounds with *A* = K, Rb, Tl/Rb and Tl/K (Fig. 7.13.15). Structure analysis of the compound $K_{0.83(2)}Fe_{1.64(1)}Se_2$ (Bao *et al.*, 2011) using NPD data indicated that at 580 K the compound has the tetragonal $ThCr_2Si_2$-type structure (*I*4/*mmm*) with lattice parameters $a_{t1} = b_{t1} =$ 3.94502 (7) Å and c_{t1} = 14.1619 (4) Å. A long-range Fe-vacancy ordering occurs below 578 K (Fig. 7.13.15*b*), with a consequent structural transition from the *I*4/*mmm* phase (*t*1) to a tetragonal *I*4/*m* superstructure phase (*t*2) with parameters $a_{t2} = b_{t2} \simeq 5^{1/2}a_{t1}$ = 8.6929 (2) Å and $c_{t2} \simeq c_{t1}$ = 14.0168 (4) Å at 11 K. In this structure model the ideal composition should be KFe_4Se_5 where for every five possible Fe positions there is one vacancy. Another model for the long-range Fe-vacancy order [Fig. 7.13.15(*c*1)] was proposed by Fang *et al.* (2011) and Kazakov *et al.* (2011) for compounds with an ideal composition AFe_3Se_4. In this model, for every four possible Fe positions there is one vacancy and consequently the superlattice has orthorhombic symmetry with unit-cell parameters $a_o \simeq 2^{1/2}a_{t1}$, $b_o \simeq 2(2^{1/2})a_{t1}$ and $c_o \simeq c_{t1}$. The models in Figs. 7.13.15(*c*1) and 7.13.15(*c*2) are the two local configurations; they have the same symmetry and cannot be distinguished by Rietveld refinement. If the two configurations

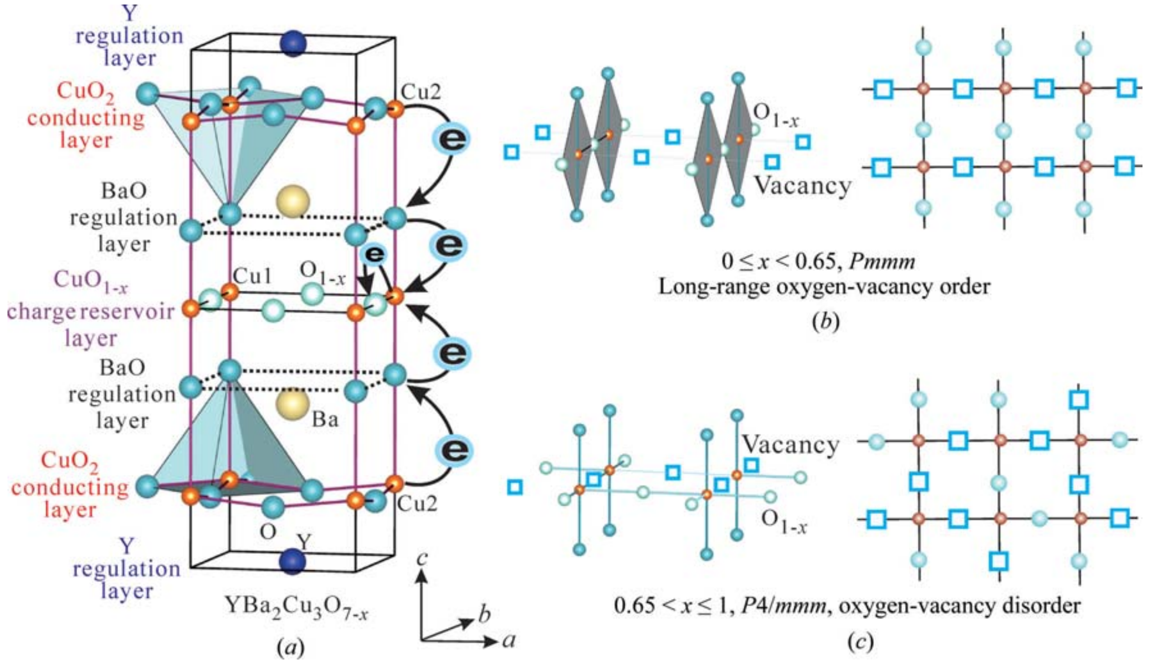

Figure 7.13.14
Structural transformation from tetragonal *P*4/*mmm* symmetry to orthorhombic *Pmmm* symmetry due to oxygen vacancy ordering in the CuO_{1-x} charge-reservoir layer. (*a*) Crystal structure of $YBa_2Cu_3O_{7-x}$. (*b*) The structure has orthorhombic symmetry when long-range oxygen-vacancy ordering occurs in the charge-reservoir layer, leaving the Cu in a CuO_4 square-planar configuration in which the Cu—O atoms form chains along the *b* axis of the unit cell. (*c*) In the range $0.65 < x \le 1$ the structure has tetragonal symmetry, in which the oxygen vacancies are disordered, thus fragmenting the one-dimensional Cu—O chains.

are present in equal amounts, one will get an average structure from powder diffraction. Therefore, the structure has an orthorhombic superlattice which is related to the tetragonal modification by the relations $a_o' \simeq b_o' \simeq 2^{1/2}a_{t1}$ and $c_o' \simeq c_{t1}$, as shown in Fig. 7.13.15(*c*).

Remarks. Since powder diffraction measures the average long-range-ordered structure, the local short-range-ordered structure might not be detected. In the $A_xFe_{2-y}Se_2$ system, the compositions of the compounds are very variable and the long-range Fe-vacancy ordering is achieved by diffusion in the solid state at a relatively low temperature. One cannot expect to reach a complete long-range Fe-vacancy order and a homogeneous distribution of vacancies in a bulk sample or a single crystal. The local structure, therefore, could be very complicated. The electron-diffraction method and/or pair distribution function (PDF) analysis can be used to obtain local structure information.

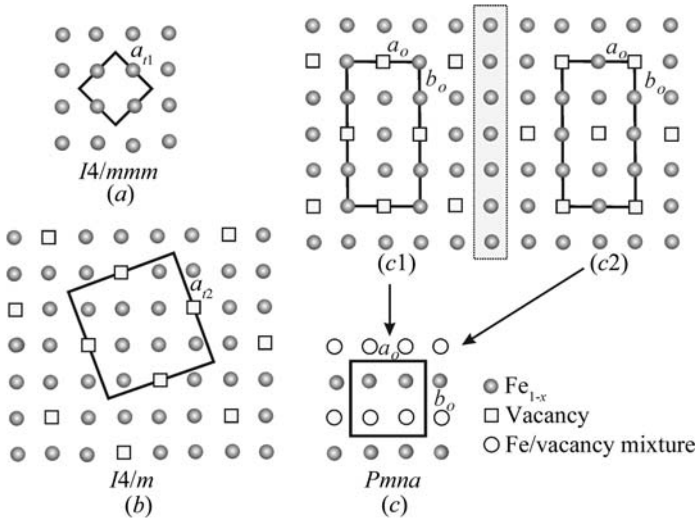

Figure 7.13.15
Possible vacancy-ordering arrangements in the Fe plane for $A_xFe_{2-y}Se_2$. (*a*) At high temperature the compound has no vacancies and forms the $ThCr_2Si_2$-type structure (*I*4/*mmm*). (*b*) One type of vacancy-ordering arrangement in the composition near $A_xFe_4Se_5$ where for every five Fe positions there is one vacancy. (*c*1), (*c*2) A proposed type of local vacancy-ordering configuration for the composition near $A_xFe_3Se_4$ where only three-quarters of the possible Fe positions are occupied (Fang *et al.*, 2011; Kazakov *et al.*, 2011). (*c*) In a powder-diffraction experiment, the pattern will show the average of the (*c*1) and (*c*2) domains resulting in an orthorhombic *Pmna* symmetry.

Substitution effects. In the $LaFeAs(O_{1-x}F_x)$ system, the parent compound ($x = 0$) has tetragonal *P*4/*nmm* symmetry at room temperature and an orthorhombic *Cmma* lattice at low temperature. However, the tetragonal *P*4/*nmm* phase is stabilized at low temperatures by partial replacement by fluorine for oxygen, *i.e.* by adjusting the dopant F concentration *x* (Zhao *et al.*, 2008; Huang *et al.*, 2008).

7.13.4. Magnetic order in superconductors and parent compounds

The interaction between superconductivity and magnetic properties is one of the most striking physical phenomena in this field. In a superconductor, in general, electrons can be in a superconducting state and/or in a magnetic state at low temperature. The study of the effects associated with the interaction between superconductivity and magnetism is a very active area of research for understanding the mechanism of superconductivity and whether superconductivity and magnetic order can coexist microscopically. Scientists have invested significant effort in investigating the magnetic properties of superconductors using different techniques, focusing on the high-T_c superconducting systems such the layered cuprates (Lynn & Skanthakumar, 2001; Niewa *et al.*, 2011), Fe-based compounds, borocarbides (Müller & Narozhnyi, 2001; de la Cruz *et al.*, 2008) and HF superconductors. Common features of the magnetic structures are:

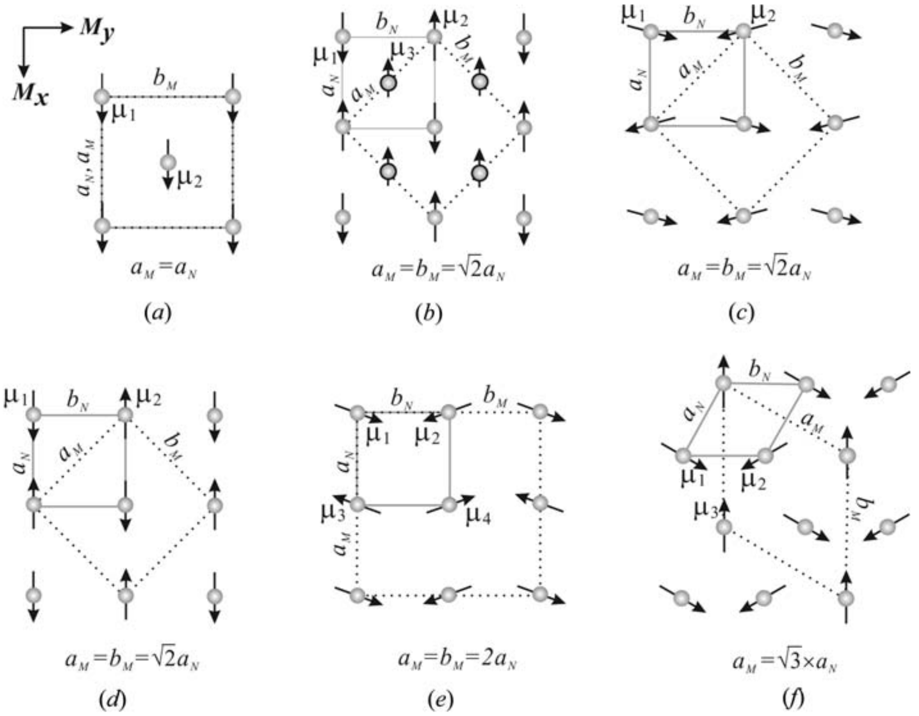

Figure 7.13.16

Representation of selected commensurate ferromagnetic and antiferromagnetic ordering schemes. Arrows show the magnitudes and directions of the moments. The crystallographic primitive unit cell is indicated by solid lines and the dotted lines show a possible magnetic unit cell. $a_N = b_N$ are the lattice parameters for the nuclear structure and a_M and b_M are those of the magnetic unit cell. (*a*) Ferromagnetic order; (*b*) a ferrimagnetic order; (*c*) a canted ferromagnetic order; (*d*) a collinear antiferromagnetic order; (*e*) a canted non-collinear antiferromagnetic order where both the $\mathbf{M}_x$ and $\mathbf{M}_y$ directions have antiparallel components; (*f*) an example of a triangular antiferromagnetic structure in hexagonal and trigonal crystals.

(i) Long-range antiferromagnetic ordering is present in some superconductors and related compounds containing rare-earth elements and/or transition metals.

(ii) In transition-metal compounds the ordering occurs at much higher temperatures and with considerably smaller moments than for compounds containing rare-earth elements. The ordering also occurs at much higher temperatures in compounds containing both types of elements.

(iii) Magnetic ordering is strongly correlated to chemical composition (including replacement and doping), crystal structure and superconductivity.

(iv) Magnetic ordering in some compounds containing rare-earth elements can coexist with superconductivity. It is questionable whether such coexistence can be present for transition metals located in the conducting layers.

NPD is essential for investigating magnetic materials, *e.g.* to determine the long-range order of magnetic structures and to measure the ordered magnetic moments (Cox, 1972).

7.13.5. Conclusions

Superconductivity can be shown by elements, alloys, intermetallics and chemical compounds of more complex compositions, and can be found in either stoichiometric or nonstoichiometric compounds. In general, the properties of superconductivity depend on the structure, *i.e.* the symmetry, the chemical composition, and the distribution of the atoms and/or ions in the structure under particular conditions (such as temperature, magnetic field and pressure). Powder diffraction has been widely and effectively employed to provide structural information and, combined with other tools or special techniques, to reveal the relationships between structure and superconductivity. As in many other research fields in materials science, powder diffraction is used to identify and to characterize the phase, to find the optimal composition, to study phase diagrams, and to determine the crystal and magnetic structures.

APPENDIX A7.13.1

The study of long-range magnetic order in superconductors

Magnetic properties have been described briefly by Borovik-Romanov *et al.* in Chapter 1.5 of *International Tables for Crystallography* Volume D (2013). Like crystal structures, the parameters of magnetic structures include the magnetic unit cell, the lattice, the magnetic moments, the symmetry elements and the space group. The moments can be arranged in parallel and antiparallel configurations, and the 14 Bravais lattices of classical crystallography become 36 magnetic lattices (Zamorzaev, 1957*a*,*b*). An additional element, 'antisymmetry', is produced by introducing the time (or current) reversal operator *R*, which acts in combination with a normal symmetry operation. With the antisymmetry element, and based on the symmetry of the 230 space groups, 1651 magnetic space groups (Shubnikov groups) have been derived [Shubnikov (1951); Belov *et al.* (1957); see also Chapter 3.6 in *International Tables for Crystallography* Volume A (Litvin, 2016)]. This section deals only with the basic magnetic crystallography related to investigations of long-range magnetic order in superconductors and in related materials, analysed using NPD.

A7.13.1.1. Commensurate magnetic ordering and primitive cells

The periodicity of a magnetic unit cell is consistent with the arrangement of the magnetic moments in addition to that of the atomic distribution. A schematic representation of the simplest types of ferromagnetic and antiferromagnetic moment arrangements (Fig. 7.13.16) helps to show the relationship between the

Table 7.13.3
Crystal systems, conventional coordinate systems and the 36 magnetic lattices in three dimensions

In the orthorhombic system, lattices with a different white lattice and location of black lattice (as indicated by the subscript) are shown in parentheses (see Section A7.13.1.2).

System	Symbol	Conventional coordinate system		Symbols of the 36 magnetic lattices	
		Restrictions on cell parameters	Parameters to be determined	White	White and black
Triclinic	a		$a, b, c, \alpha, \beta, \gamma$	aP	aP_s
Monoclinic	m	$\alpha = \gamma = 90°$	a, b, c, β	mP, mC	mP_b, mP_a, mP_C, mC_c, mC_a
Orthorhombic	o	$\alpha = \beta = \gamma = 90°$	a, b, c	oP, oI, oF (oC, oA)	oP_I, oF_s, oI_c (oP_C, oP_A) (oC_A, oA_C) (oP_c, oP_a) (oC_c, oA_a) (oC_a, oA_c)
Tetragonal	t	$a = b$, $\alpha = \beta = \gamma = 90°$	$a = b \neq c$	tP, tI	tP_c, tP_C, tP_I, tI_c
Trigonal	h	$a = b = c$, $\alpha = \beta = \gamma$	a, α	hR	hR_I
Hexagonal	h	$a = b$, $\alpha = \beta = 90°$, $\gamma = 120°$	a, c	hP	hP_c
Cubic	c	$a = b = c$, $\alpha = \beta = \gamma = 90°$		cP, cF, cI	cP_I, cF_s

unit cells of the nuclear and magnetic structures. For simplicity, only the *ab* plane in a tetragonal [(*a*)–(*e*)] and a hexagonal (*f*) structure is shown ($a_N = b_N$ are the nuclear and a_M and b_M are the magnetic unit-cell parameters).

Ferromagnetic ordering (Fig. 7.13.16*a*). Ferromagnetic order often involves only one kind of magnetic ion or atom and the spontaneous magnetization is uniform ($\boldsymbol{\mu}_1 = \boldsymbol{\mu}_2$), *i.e.* their magnetic moments have the same amplitude and are aligned parallel and in the same direction to each other. In this case, the magnetic structure has the same unit cell as the nuclear unit cell, *i.e.* $a_N = a_M$ and $b_N = b_M$. Therefore, it should be possible to index the magnetic reflections in an NPD pattern using the nuclear unit cell and the magnetic intensities will overlap with the nuclear peaks.

Ferrimagnetic ordering (Fig. 7.13.16*b*). In this example of ferrimagnetic order, all the moments have parallel alignment but have different amplitudes. The magnetic ions or atoms at the corners of the nuclear unit cell are aligned antiferromagnetically and have different moment amplitudes to the ones at the centre. The system has a net ferromagnetic moment $\boldsymbol{\mu} = \boldsymbol{\mu}_1 - \boldsymbol{\mu}_2 + \boldsymbol{\mu}_3 = \boldsymbol{\mu}_3$. The magnetic unit cell can be $a_M = 2a_N$ and $b_M = 2b_N$ or $a_M = b_M = 2^{1/2}a_N$ (indicated by dotted lines). In this case magnetic reflections corresponding to the magnetic superlattice should be observed in the NPD pattern.

Canted ferromagnetic ordering (Fig. 7.13.16*c*). The canted ferromagnetic order shown in the figure is a simple non-collinear structure generated by the tilting of the $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ moments. In this case the system possesses a net ferromagnetic moment; components in the $\mathbf{M}_x$ direction are ferromagnetic and the moment component in the $\mathbf{M}_y$ direction has an antiferromagnetic arrangement. The magnetic unit cell can be obtained by doubling a_N and b_N, or $a_M = b_M = 2^{1/2}a_N$ (dotted lines). The canted

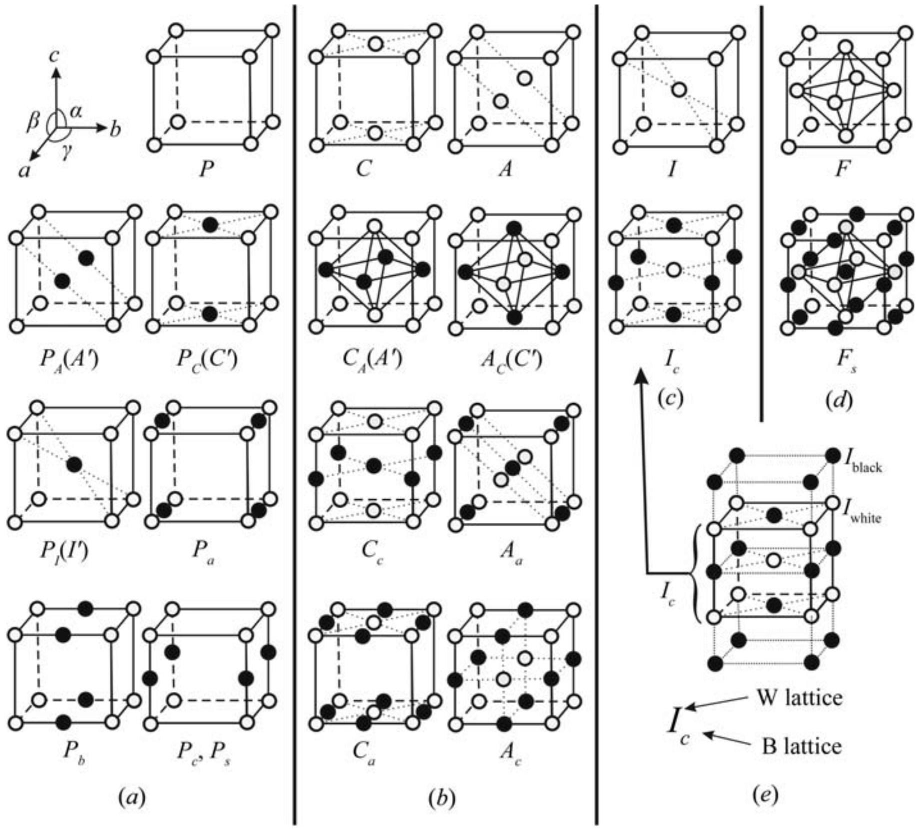

Figure 7.13.17
Types of magnetic lattices. The first row are the five white lattices *P*, *C*, *A*, *I* and *F*. The other white-and-black lattices can be constructed by combination of a white lattice with its corresponding black lattice, with the black lattice having its origin at the face centre or edge centre or body centre of the white lattice [indicated by the subscript, see (*e*)].

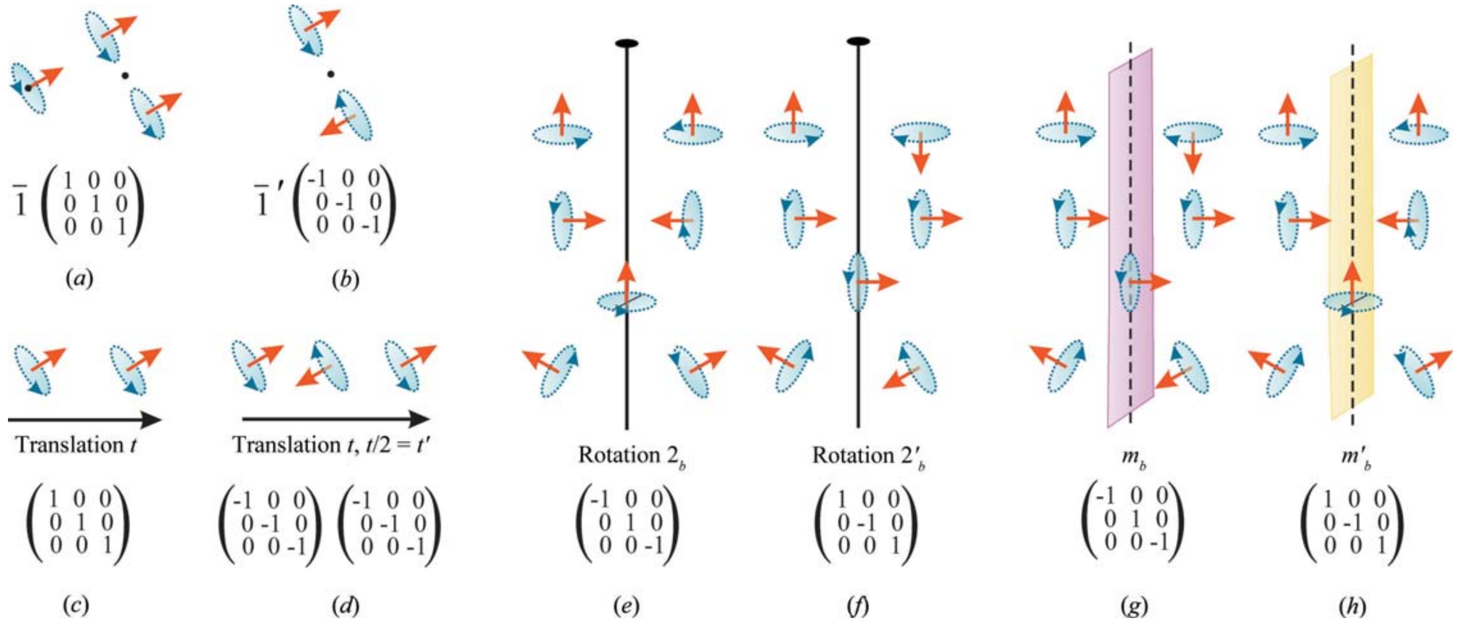

Figure 7.13.18

Selected magnetic symmetry and antisymmetry elements that Dannay *et al.* (1958) first applied to magnetic symmetry. (*a*) Inversion $\bar{1}$; (*b*) anti-inversion $\bar{1}'$; (*c*) translation *t*; (*d*) anti-translation *t*′; (*e*) rotation 2; (*f*) anti-rotation 2′; (*g*) reflection *m*; and (*h*) anti-reflection *m*′.

ferromagnetic moments have a ferromagnetic component and an antiferromagnetic component.

Collinear antiferromagnetic ordering. An example of collinear antiferromagnetic ordering is shown in Fig. 7.13.16(*d*). In this case there is only one type of ion (or atom), located in equivalent crystallographic positions and having equal moment amplitudes in an antiparallel orientation.

Canted antiferromagnetic ordering. Fig. 7.13.16(*e*) shows an example of a canted non-collinear antiferromagnetic order in which the moments tilt in such a way that both the $\mathbf{M}_x$ and $\mathbf{M}_y$ directions have antiparallel components. The magnetic unit cell has parameters that are double those of the nuclear unit cell.

A7.13.1.2. *The 36 magnetic lattices and 1651 Shubnikov groups*

The types of magnetic lattices are shown in Fig. 7.13.17. They are similar to the familiar crystal lattices in that they represent identical chemical entities, but the associated magnetic moments have the same amplitude and opposite orientation. The first row of the figure shows five types of white lattices: *P* (primitive), *C* (*C*-face centred), *A* (*A*-face centred), *F* (all-face centred) and *I* (body centred). All the white lattices represent ferromagnetic ordering of the moments. A white-and-black (W&B) lattice can be thought of as containing two lattices of the same type, one of which is termed 'white' and the other 'black'. The origin of the black lattice can be located at the centre of a face or at an edge, or at the body centre of the white lattice. For example, Fig. 7.13.17(*e*) indicates a white *I* lattice combined with a black *I* lattice with origin at *c*/2 of the white lattice, resulting in the W&B lattice I_c of Fig. 7.13.17(*c*). The W&B lattices are expressed by two-letter symbols in which the symbol (*P*, *C*, *A*, *I* or *F*) of the W lattice is followed by a subscript (*A*, *a*, *C*, *c*, *I* or *s*) which indicates the location of the origin of the black lattice. The capital subscript letters *A*, *C* and *I* indicate that the origin of the B lattice is at the *A*-face centre (0, *b*/2, *c*/2), *C*-face centre (*a*/2, *b*/2, 0) and at the body centre (*a*/2, *b*/2, *c*/2) of the white lattice, respectively. The lower-case subscript letters *a* and *c* indicate that the origin of the black lattice is at the centre of the *a* axis (*a*/2) and *c* axis (*c*/2) of the white lattice, respectively. For example, the lattice P_C is a combination of a *P* W lattice with a *P* B lattice with the origin at the *C*-face centre ($\frac{1}{2}$, $\frac{1}{2}$, 0) of the W lattice, while P_c indicates that the origin of the *P* B lattice is at *c*/2. These types of magnetic lattices, when applied to the seven crystal systems, give a total of 36 magnetic lattices, of which 14 are pure white and 22 are W&B lattices (see Table 7.13.3).

A7.13.1.3. *Magnetic symmetry and antisymmetry operations*

Magnetic symmetry elements include all the symmetry elements of the nuclear structure plus the corresponding antisymmetry elements that are produced by adding the time (or current) reversal operation *R*. Selected typical elements of symmetry and antisymmetry and their symmetry-operation matrices are shown in Fig. 7.13.18. The operation of an element of antisymmetry can be performed as a normal symmetry operation followed by a reversal in direction.

A7.13.1.4. *Magnetic reflection conditions for centred lattices*

Table 7.13.4 lists the possible neutron magnetic reflection conditions related to the magnetic lattices illustrated in Fig. 7.13.17. The results are obtained by evaluating the neutron magnetic structure factor for $F_{hkl} = 0$ and are confirmed by computations using the program *GSAS* (Larson & Von Dreele, 2004). The conditions for systematic extinctions of magnetic reflections for glide planes and screw axes were reported by Ozerov (1967).

Effects of spin orientation in magnetic structures. Fig. 7.13.3 is a schematic view of the definition of the vectors relevant to the evaluation of the magnetic structure factor. In addition to the magnetic reflection conditions for centred lattices, glides and screws, systematic absences can also be observed when the condition $F_{hkl} = 0$ occurs because the magnetic spin **K** is parallel to the scattering vector $\boldsymbol{\varepsilon}$ for a class of reflections *hkl*. In this case, the angle α between the scattering and the magnetization vectors is zero and, consequently, $|q| = \sin\alpha = 0$.

Ambiguous spin orientation. Shirane (1959) showed that ambiguous spin structures can be deduced from NPD data, and concluded that: (i) no information can be obtained about the spin

Table 7.13.4
Integral reflection conditions of centred magnetic lattices corresponding to Fig. 7.13.17

In the symbols for the W&B lattices, the first letter indicates the W lattice (P, C, A, I and F) and the subscript indicates the B lattice.

Type of magnetic lattice and origin for B lattice			Condition for *hkl* reflection	
W	W&B	Origin of B lattice	W lattices	W&B lattices
P				
	P_A	A-face centre, $(b + c)/2$		$k + l = 2n + 1$
	P_C	C-face centre, $(a + b)/2$		$h + k = 2n + 1$
	P_I	I (body) centre, $(a + b + c)/2$		$h + k + l = 2n + 1$
	P_a	a-axis centre, $a/2$		$h = 2n + 1$
	P_b	b-axis centre, $b/2$		$k = 2n + 1$
	P_c, P_s	c-axis centre, $c/2$		$l = 2n + 1$
C			$h + k = 2n$	
	C_A	A-face centre, $(b + c)/2$	$h + k = 2n$	$k + l = 2n + 1$
	C_c	c-axis centre, $c/2$	$h + k = 2n$	$l = 2n + 1$
	C_a	a-axis centre, $a/2$	$h + k = 2n$	$h, k = 2n + 1$
A			$k + l = 2n$	
	A_C	C-face centre, $(a + b)/2$	$k + l = 2n$	$h + k = 2n + 1$

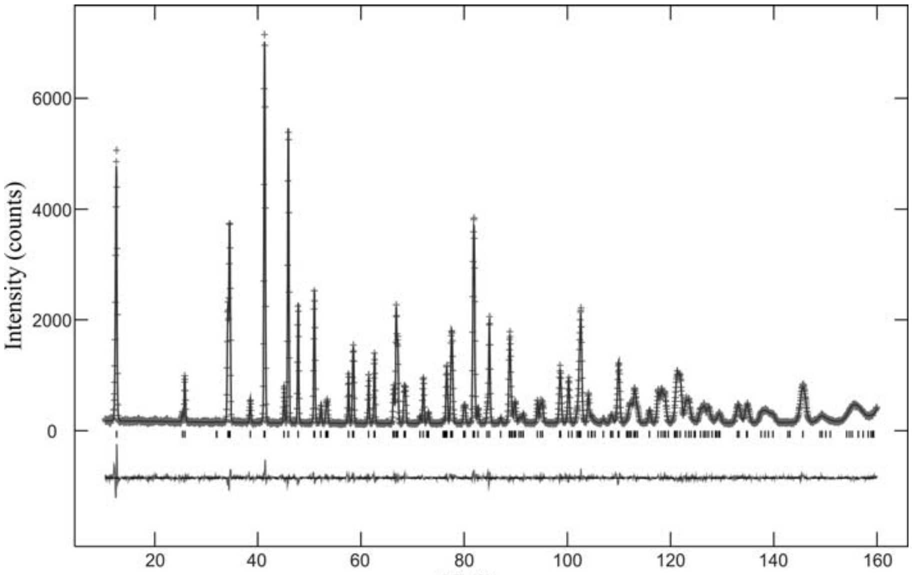

Figure 7.13.19
Observed (crosses) and calculated (solid line) intensities of neutron powder diffraction intensity data for the superconductor NaFeAs at 5 K. Possible Bragg positions are shown by vertical lines and the differences between the observed and calculated intensities are shown at the bottom of the figure.

direction if the symmetry is cubic; and (ii) in tetragonal and rhombohedral or hexagonal symmetries, the powder-diffraction intensities can only provide the angle between the spin direction and the unique c axis of the structure.

A7.13.1.5. An example of Rietveld refinement against NPD data for a superconductor

A plot of NPD intensity data for the superconductor NaFeAs (Li *et al.*, 2009) is given in Fig. 7.13.19. The data were measured on the BT-1 high-resolution powder diffractometer at the NIST Center for Neutron Research. A monochromatic neutron beam was produced using a Cu(311) monochromator (λ = 1.5403 Å) and three collimators with horizontal divergences of 15, 20 and 7′ full width at half-maximum (FWHM) before and after the monochromator, and after the sample. The crystal structure was refined using *GSAS* (Larson & Von Dreele, 2004). The raw data and the data-collection conditions in *GSAS* format are given in the supporting information as files NPD-NCNR_BT1 NaFeAs at 5K.gsas and NCNR-BT1_MonoCu311.inst, respectively. The initial structural model was obtained from the ICSD database (code 165997).

The author is grateful to the referee Dr Georg Roth for his very constructive comments and suggestions for the final version of this chapter. The author also acknowledges Dr J. K. Liang of the Institute of Physics, Chinese Academy of Science, Dr R. J. Cava of Princeton University, and Drs R. Erwen, J. W. Lynn, H. Wu and A. Santoro of the NIST Center for Neutron Research for helpful discussions.

7.14. Powder diffraction by minerals

R. Arletti, G. Cruciani and G. Ferraris

Unravelling the complexity and diversity of mineral structures is one of the most important topics in modern mineralogy. Knowledge of mineral composition, crystal structure, properties and occurrence is a source of inspiration and novel ideas not only for the Earth and planetary sciences, but also for materials science and modern technologies. These data have established a framework for developing the innovative concept of 'mineral evolution' (Hazen & Ferry, 2010), which focuses on changes in the composition, association, diversity and structural complexity of near-surface minerals through time on the Earth. An important advantage of the powder method over single-crystal methods is that the results might be more representative of the sample that is being investigated. In a single-crystal diffraction experiment, it is possible to obtain detailed information only on individual crystals, with all their individual particularities, which might differ substantially from one crystal to another. Instead, powder methods average over millions of crystallites and are thus more representative, for example, for a mineral species. In another very important respect, powder-diffraction methods allow the quantitative study of mineral mixtures, which is of primary importance for determining mineral paragenesis and investigating mixed crystals.

An understanding of mineral transformation processes (and of material transformations in general) is extremely important in several areas of earth and materials sciences.

Fig. 7.14.1 clearly indicates the strong increase in the number of scientific publications related to the study of minerals with X-ray powder diffraction in the last decade. The technical proficiencies of XRPD laboratories have developed strongly in the last few years, especially in relation to *in situ* powder-diffraction studies.

In situ investigations enable observation of the evolution of a material subjected to external perturbation (*e.g.* high temperature, high pressure, magnetic/electric fields *etc.*), as well as monitoring material processing (*i.e.*, crystallization, dehydration, catalytic reactions, Portland cement production and hydration, *etc.*). In order to fully capture the process dynamics, the measuring time needs to be shorter than the timescale of the process itself, allowing the collection of multiple snapshots at different stages. Thanks to the development of fast detectors, experiments at non-ambient conditions [*i.e.*, high temperature (HT) and high pressure (HP)] can be carried out in dynamic mode, enabling the recording of the sample evolution in time- or temperature-resolved conditions with a time resolution from minutes down to seconds. In recent decades, *in situ* powder-diffraction techniques based on synchrotron (or neutron) radiation have been successfully applied to study the process dynamics of transformations in minerals and their synthetic counterparts. The main advantages of time-resolved experiments are the possibility of gaining insights into transient and intermediate states of processes and to record non-quenchable structural modifications at conditions 'far from the equilibrium'.

In this chapter, we demonstrate how XRPD, alone or in conjunction with other methods, is a suitable technique for the structural characterization of minerals and their synthetic counterparts. Examples are presented in which powder diffraction is the main technique, together with case studies in which it is used in combination with other techniques. Many of the case studies involve rock-forming and hydrated minerals. Special emphasis is given to zeolites because these minerals – apart from being particularly complex and challenging in their structures – are also involved in many intriguing phenomena, as detailed later.

7.14.1. Powder diffraction and characterization of new mineral species

Searching for and characterizing new mineral species is a very active field in the mineralogical sciences, particularly in the sector of mineralogical crystallography and crystal chemistry. Sometimes even rare non-rock-forming minerals may be the basis for discovering and understanding unsuspected geological phenomena. A good example is the importance of the high-pressure silica phase coesite (Chopin, 1984) for the development of high-pressure metamorphic petrology. At the same time, the discovery of novel structural types that often occur in new minerals may offer inspiration for materials science (*e.g.* Ferraris & Merlino, 2005). The official list of mineral species approved by the Commission on New Minerals, Nomenclature and Classification (CNMNC) of the International Mineralogical Association (IMA) (http://nrmima.nrm.se/) includes some 5000 items. Apart from a very few cases (*e.g.* allophane, mercury, opal), minerals are crystalline materials and the procedures for submitting a proposal for the approval of a new mineral species (Nickel & Grice, 1998) require that the submitted data include a powder-

diffraction pattern suitable for later identification of the crystalline materials by searching specialized databases [*e.g.* the Powder Diffraction File (PDF), from the International Centre for Diffraction Data (ICDD), http://www.icdd.com/products/pdf4-minerals.htm, and RRUFF, http://rruff.info/].

In recent years, the IMA list of minerals has increased at a rate of about 100 new species per year, mainly because modern experimental methods (*e.g.* single-crystal diffraction using focusing X-ray optics or synchrotron radiation; electron diffraction tomography techniques; electron microprobe chemical analysis; electron backscatter diffraction) allow characterization of new mineral species from submicrometre-sized coherent domains of a single or mosaic crystal. In extreme cases, powder-diffraction data can also be acquired and recovered through: (i) the Gandolfi method, using either a specialist camera or a single-crystal diffractometer *via* a simulation routine; (ii) collapsing a three-dimensional (3D) single-crystal diffraction pattern to 1D; or (iii) calculating a powder-diffraction pattern from a crystal structure.

The lack of availability of large single crystals makes the use of powder-diffraction data for crystallographic characterization of new and rare minerals unavoidable, but it is also the best method for characterizing real minerals, as exemplified in the following case studies.

Anthoinite, $AlWO_3(OH)_3$, is available only as microcrystalline masses, and its layered triclinic structure was solved by applying *ab initio* methods to both X-ray and neutron powder-diffraction data, and then refined using the Rietveld method (Grey *et al.*, 2010).

The close similarities, both in chemical formulae and powder-diffraction patterns between the known pokrovskite, $Mg_2(CO_3)(OH)_2$, and the new mineral chukanovite, $Fe_2(CO_3)(OH)_2$, suggested a reliable starting model for the latter phase, which was successfully refined by the Rietveld method using synchrotron X-ray diffraction data (Pekov, Perchiazzi *et al.*, 2007).

Because of a complex pseudocubic twinning, the orthorhombic structure of lakargiite, $CaZrO_3$, could only be unravelled by combining single-crystal (cell parameters) and X-ray powder-diffraction data (solution and refinement) (Galuskin *et al.*, 2008).

The molybdoarsenates betpakdalite, natrobetpakdalite and obradovicite, as well as the molybdophosphates mendozavilite, paramendozavilite and melkovite, typically occur as coatings of minute, poor-quality and/or complexly twinned crystals. Comparative X-ray powder diffraction proved effective in identifying structurally related phases and obtaining refined cell parameters for those phases for which single-crystal studies could not be conducted (Kampf *et al.*, 2012).

Only curved and split crystals are known for gjerdingenite-Na, $(K,Na)_2Na(Nb,Ti)_4(Si_4O_{12})_2(OH,O)_4\cdot 5H_2O$, and gjerdingenite-Ca, $K_2Ca(Nb,Ti)_4(Si_4O_{12})_2(O,OH)_4\cdot 6H_2O$, two new mineral species of the labuntsovite group. Thus, their crystal structures were refined from X-ray powder-diffraction data starting from the coordinates of other members of the group (Pekov, Chukanov *et al.*, 2007).

Owing to the lack of suitable single crystals, the crystal structure of the new mineral jadarite, $LiNaSiB_3O_7(OH)$, was solved from laboratory powder-diffraction data and even the H atoms were located by applying *ab initio* optimization (Whitfield *et al.*, 2007).

Using synchrotron X-ray microdiffraction, diffraction patterns combining powder and single-crystal features can be obtained. Chladniite is a complex phosphate species belonging to the fillowite group first found in meteorites and recently also identified in a pegmatite from Córdoba (Argentina). Using the latter material and applying a synchrotron through-the-substrate microdiffraction technique to polished thin sections prepared on very thin glass substrates (0.1 mm), diffraction data were obtained with nearly single-crystal quality, allowing the crystal structure of chladniite to be solved (Vallcorba *et al.*, 2017).

Reflection overlap and peak-profile broadening in XRPD patterns can increase uncertainty in intensity determination and thus hinder structural studies, especially in relation to nanophases. In the field of structure determination, electron diffraction (ED) has recently been proved to be a perfect complementary tool to XRPD. While the potential use of ED for structure solution has been known for a long time (*e.g.* Rigamonti, 1936), its routine applicability has been severely hampered by the presence of marked dynamic effects and the high electron dose usually required to illuminate the sample, leading to rapid modification of the crystalline structure or complete amorphization. Nevertheless, high-resolution transmission electron microscopy (HRTEM) could access direct-space structural information down to a resolution of 0.8–0.5 Å from crystal nanodomains (Kisielowski *et al.*, 2008; Haider *et al.*, 1998). A breakthrough came with the use of precession electron diffraction (PED) to reduce the dynamic effects (Vincent & Midgley, 1994), paving the way for an increasing number of structure solutions obtained from PED data (*e.g.* Gemmi *et al.*, 2010; Palatinus *et al.*, 2013). A further step ahead was the recent development of automated diffraction tomography (ADT), allowing an automated procedure for 3D electron-diffraction data acquisition and processing (Kolb *et al.*, 2007, 2008). Electron-diffraction intensity data sets collected with ADT include large numbers of high-index reflections, which is highly advantageous for achieving a starting crystal-structure model (Mugnaioli *et al.*, 2009) that can be then used as input to refinements using XRPD data.

7.14.2. Mineral physics through *in situ* powder-diffraction experiments

7.14.2.1. *Thermoelastic behaviour of minerals*

A description of rock-forming minerals at the atomic scale is fundamental for the understanding the Earth's mineralogical composition and rheological properties. Another crucial issue for the progress of the Earth sciences is determining the stability of mineral phases under non-ambient conditions, *i.e.* understanding the structural modifications occurring in minerals subjected to pressures and temperatures comparable to the interior of the Earth. Transformations in Earth materials induced by pressure, as well as the combined effects of pressure and temperature, are the key to interpreting phenomena such as seismic discontinuities or the existence of elastic anisotropies in the deep Earth. Defining the full framework of dynamic processes therefore requires detailed studies of the structure, bonding and electronic properties of component minerals, and establishing the effects of extreme conditions on their physical and chemical properties. These aims are now achievable owing to the development of diamond anvil cell (DAC) techniques and *in situ* methods using synchrotron radiation. Recent structural studies indicate that the properties of many materials are strongly altered under deep Earth conditions, giving rise to transformations that cannot be ascertained from studies of the same materials at near-ambient conditions (Hemley *et al.*, 2000). These modifications include crystal-structure transformations (*i.e.*, reconstructive, displacive, order–disorder *etc.*), electronic changes (including spin-crossover, band structure, bonding and insulator–metal transitions) and magnetic transitions. The first experimental studies on minerals and rocks under HT and HP date back to the end of the eighteenth century in a series of melting and crystallization experiments. In the following centuries, a lot of progress was achieved and the impact on the earth sciences was enormous.

The lower mantle is the largest single region in the Earth's interior, and the definition of a thermoelastic model for deep-mantle minerals is of great interest (*e.g.* Chinnery *et al.*, 2000; Fiquet *et al.*, 2002; Andrault *et al.*, 2003; Merkel *et al.*, 2007; Kubo *et al.*, 2008). By the first half of the twentieth century, the presence of the main seismic discontinuity was established and linked to the phase transitions olivine–spinel and spinel–perovskite (Pv). For a long time, the $MgSiO_3$ perovskite was believed to be stable throughout the entire mantle, but, synchrotron powder-diffraction experiments (Murakami *et al.*, 2004; Iitaka *et al.*, 2004) indicated a phase transition at 125 GPa and 2500 K, corresponding to the D′′ seismic discontinuity, later established to be post-perovskite (pPv). The crystallographic models derived from the experiments showed that the pPv phase arises from the tilting of octahedral chains in the Pv structure. The pPv phase exhibits large structure anisotropy compared with the Pv phase. The transition is unquenchable to ambient conditions. The evolution of octahedral tilting upon compression is also a widely investigated topic in synthetic perovskites because of their interesting multiferroic (ferroelectric and ferromagnetic) properties. The contrasting HP behaviour of $A^{3+}B^{3+}O_3$ *versus* $A^{2+}B^{4+}O_3$ perovskites has attracted particular interest (*e.g.* Ardit *et al.*, 2010). Octahedral tilting is expected to increase in $A^{3+}B^{3+}O_3$ and decrease in $A^{2+}B^{4+}O_3$, thus leading to low- and high-symmetry phase transitions, respectively. Understanding the rheological properties of mantle minerals is necessary to follow the mechanism of solid-state convection in the Earth. The development of HP apparatus is required for quantitative studies of pressure strength and mantle rheology under challenging *in situ* conditions (Duffy, 2005). Advanced methods for measuring and interpreting lattice-strain anisotropy using XRPD have led to significant advances in the characterization of elastic anisotropy and texture development in materials of geological interest (Merkel, 2006; Singh, 2014).

Apart from the great interest in modelling the seismic behaviour of the Earth's lower mantle, an understanding of processes involving the crust and upper mantle is of fundamental importance. The extrapolation of equilibrium curves to the P–T conditions of the lower crust and upper mantle is an intriguing challenge, since these curves are sometimes quite inconsistent as regards the $\mathrm{d}P/\mathrm{d}T$ slope and absolute position, especially for reactions containing hydrous phases. For this reason, it is very important to collect thermophysical data [*i.e.*, data on the bulk modulus, $K_T = -V(\partial P/\partial V)_T$, and thermal expansivity, $\alpha = (1/V)(\delta V/\delta T)_P$] for high-pressure hydrous phases, which are stable in the lower crust and mantle regions, and calculate their equations of state (Grevel *et al.*, 2000; Welch & Marshall, 2001; Walter *et al.*, 2015).

7.14.2.2. *Negative thermal expansion in minerals*

The vast majority of solids expand when heated, a property that can create problems in some HT processes. However, certain materials exhibit negative thermal expansion (NTE) with volume contraction on heating, a phenomenon occurring, for example, in some metal oxides and zeolites (*e.g.* Marinkovic *et al.*, 2009; Leardini *et al.*, 2015). Detailed studies of these cases enable the development of new materials with coefficients of thermal expansion (CTE) equal to zero. NTE generally derives from cooperative or supramolecular structural mechanisms that prevail over the positive thermal expansion of interatomic bonds. These mechanisms include (i) transverse bond vibrations and libration; (ii) rigid unit modes (RUMs); (iii) phase transitions; (iv) cracking (Miller *et al.*, 2009); and (v) elastic recovery of transient deformations (Cruciani & Gualtieri, 1999). Understanding the mechanisms behind NTE behaviour is crucial for tailoring natural and synthetic materials to exhibit specific expansion properties. For instance, the creation (engineering) of overall zero thermal expansion (ZTE) materials can be achieved by using NTE parts as thermal-expansion compensators.

In situ XRPD coupled with Rietveld structural analysis is a powerful tool for quantifying and explaining the thermal expansion of materials. In the widely investigated field of porous materials, knowing the thermal-expansion coefficients of a particular zeolite is of paramount importance in many applications, including the prediction of possible mechanical issues in supported polycrystalline zeolitic membranes. Understanding the mechanisms governing heat-induced structural deformations is particularly crucial in, for example, aerospace technologies, microchips and optical devices.

Among the porous materials studied under HT, the pure silica zeolites and molecular sieves ITQ-1, ITQ-3, SSZ-23, ITQ-4, faujasite and ZSM-5 exhibit marked NTE (*e.g.* Woodcock *et al.*, 1999). Since NTE depends on lattice-dynamic effects, in zeolites it can be modified by the isomorphous substitution of heteroatoms in the framework. The dependence of NTE, and of thermal-expansion behaviour in general, on heteroatom substitution has been explored for zeolites sharing an MFI-type framework by *in situ* XRPD. It was demonstrated that the substitution of Si with metals enhances thermal contraction. HT-XRPD studies carried out on the metallosilicate molecular sieves Fe-silicalite-1 with different Si/Fe ratios (Si = 50, 75 and 100%) found that all the samples exhibited NTE in the temperature range 373–773 K with increasing strength as the Fe content rises (Bhange & Ramaswamy, 2010). The kind of heteroatom also affects the extent and strength of NTE in MFI topology (Bhange & Ramaswamy, 2007).

The NTE phenomenon has also been investigated for other minerals. For instance, cuprite (Cu_2O), besides being a mineral with a very small thermal-expansion coefficient, exhibits NTE in the temperature range 9–200 K, and then positive expansion up to the decomposition temperature (630 K). Synchrotron powder diffraction coupled with EXAFS showed that NTE effects observed in cuprite-type compounds depend on the transverse motion of the metal atoms perpendicular to the O–M–O linear bonds (Artioli *et al.*, 2006).

7.14.2.3. *Dehydration of nonporous minerals*

'Water' (more correctly, H_2O or OH^- or H^+) in minerals plays a crucial role in sustaining the geological activity of our planet by affecting melting relationships and influencing its rheology. Hence, considerable research has been carried out on the HT behaviour of hydrous mineral phases in order to understand the transport of H_2O into the Earth's interior (Nishi *et al.*, 2014; Shieh *et al.*, 2000). The water released by dehydration of a subducting oceanic slab strongly influences magmatic processes and plays an important role in seismic activity. For example, dehydration of serpentine minerals, formed from the alteration of ultramafic rocks (*i.e.*, igneous rocks with a very low silica content) and representing a major hydrous phase in the subducting oceanic plates, has attracted a lot of interest. The large amount of 'water' present in these phases (a serpentinized peridotite contains ~10% H_2O) is released in subduction zones when they break down into less-hydrated phases, thus leading to metasomatism in the overlying mantle (*e.g.* Scambelluri *et al.*, 2001, and references therein) and promoting partial melting in the mantle wedge, giving rise to arc magmatism (Ulmer & Trommsdorff, 1995). It has also been suggested that these reactions cause the seismicity observed in the subducting oceanic mantle, since dehydration may produce high pore pressures and embrittlement in lithospheric rocks (Dobson *et al.*, 2002). The stability field and dehydration rates of antigorite have been extensively studied both at ambient pressure (*e.g.* Cattaneo *et al.*, 2003) and high pressure (Perrillat *et al.*, 2005; Chollet *et al.*, 2011) to predict the depth at which fluid is released into subduction zones, indicating that serpentine dehydration is a possible explanation for intermediate-depth earthquakes.

7.14.2.4. *Dehydration and adsorption/desorption mechanisms in porous materials*

Zeolite dehydration mechanisms have been widely studied because the sorptive and catalytic properties exploited in industrial processes are typically activated by heating and are profoundly influenced by their structural behaviour at high temperature. A knowledge of the structural modifications induced by temperature and the definition of the stability field of these materials is of prime importance to assure their persistence and effectiveness in technological applications.

The development of *in situ* time- and temperature-resolved XRPD techniques, typically using synchrotron radiation, allows the process dynamics to be tracked for a continuous picture of the structural response of zeolites to dehydration. For instance, catching the short-lived 'pore-mouth breathing' motions provides information about the interplay between hydrogen bonding, thermal expansion and volume contraction in a framework structure. Monitoring $T{-}O{-}T$ angles during dehydration can provide information about the preferential diffusion path for H_2O molecules released through the channel system (Cruciani, 2006).

The thermal behaviour of natural and synthetic zeolites has been reviewed by several authors (Bish & Carey, 2001; Cruciani, 2006; Depmeier, 2009). In summary, upon heating, zeolites may undergo the following structural changes: (i) cell-volume contraction due to the removal of H_2O and/or templating organic molecules (dehydration and calcination); (ii) displacive or reconstructive phase transformation(s); (iii) breaking (and new formation) of $T{-}O{-}T$ bonds; (iv) NTE; (v) partial structural collapse with retention of some sorption properties; and (vi) structural breakdown. Among the principal factors, these effects are controlled by: (*a*) the Si/Al ratio, (*b*) the framework topology, and (*c*) the nature, number and coordination of extra-framework cations.

In addition to dehydration/rehydration dynamics, other processes such as adsorption/desorption of organic molecules by porous materials have been investigated in depth from a structural point of view through powder diffraction in recent years. Understanding the science behind adsorption processes and the interaction between adsorbent and adsorbate helps, for example, when designing sustainable water-remediation systems that exploit the capability of zeolites as adsorbing materials. An excellent example is represented by the structural studies performed by Martucci and co-workers (*e.g.* Martucci *et al.*, 2014) on high-silica zeolites used for the removal of organic pollutants (antibiotics and hydrocarbons) from waste water. It has been found that the adsorption of given organic molecules from aqueous solutions depends not only on the dimensions of the pore systems, but also on competition between the adsorbate and water, linked to the hydrophobicity of the zeolite in question.

7.14.2.5. *High-pressure (HP)-induced reaction/penetration in porous materials*

Recently it has been demonstrated through *in situ* X-ray/neutron powder-diffraction experiments that, in addition to HT, HP can also induce important structural changes in porous materials, modifying the accessibility of catalytic sites, and physical and chemical properties, and consequently feasible applications (Arletti *et al.*, 2003; Vezzalini *et al.*, 2014). In the experimental HP studies on zeolites, either 'pore penetrating' or 'non-penetrating' pressure-transmitting media (PTM) were used. The studies performed with 'non-penetrating' media highlighted that the HP-induced deformation mechanisms are controlled by tetrahedral tilting, which is strongly influenced by the framework type and composition, as well as by the extra-framework content.

The use of 'penetrating' media has been exploited in different pressure regimes to test a variety of effects of different media on microporous frameworks. It is known that compressing a zeolite with an aqueous solution can induce the pressure-induced hydration (PIH) effect (Lee *et al.*, 2002), which involves the penetration of additional H_2O molecules into the zeolite channels in response to the applied pressure. This phenomenon can be accompanied by abrupt volume expansion (*e.g.* Lee *et al.*, 2002) or, on the contrary, exhibit no cell volume expansion (*e.g.* Likhacheva *et al.*, 2006).

Not only H_2O penetration into zeolite cavities has attracted interest in recent years, but also the hyper-confinement of other guest molecules. It has been demonstrated that the confinement of organic molecules (*e.g.* ethylene, acetylene) inside zeolite channels can induce polymerization reactions, without the use of catalysts or activators (Santoro *et al.*, 2013).

The compression of zeolites in the absence of a medium or in the presence of a non-penetrating PTM is also used to induce pressure-induced amorphization (PIA). PIA is observed for a wide range of silicate structures and is characterized by important volume reductions, producing a new material denser than the corresponding crystalline and glass phases. Greaves *et al.* (2003) explored the time dependence and dynamics of zeolite amorphization generated by compression and found evidence for polyamorphism. This is the coexistence of different amorphous phases of the same composition but with different densities.

7.14.2.6. *Phase transitions and spontaneous strain in minerals*

Structural phase transitions are almost invariably accompanied by lattice strain arising from lattice distortions or relaxations on a macroscopic scale. Lattice distortions can represent the predominant driving force for a transition, as in ferroelastic transitions, or they can be a secondary response to some other driving mechanism. The excess energy deriving from a phase transition contains a component from elastic energy. The additional lattice strain (compared with the normal response of a crystal to changing temperature or pressure) associated with a phase transition is usually referred to as a spontaneous strain. Very accurate lattice distortion and strain measurements can be achieved using high-resolution powder diffraction, and provide valuable and detailed insights into the nature and mechanisms of a given phase transition. A quantitative thermodynamic analysis of spontaneous strain in ferroelastic minerals can be conveniently carried out within the theoretical framework of the Landau theory (Carpenter *et al.*, 1998).

Besides the early studies in minerals as reviewed by Carpenter *et al.* (1998), among the more recent examples of spontaneous-strain analysis combining high-resolution synchrotron and neutron powder diffraction with Landau theory is the work on (Ca,Sr)TiO_3 perovskite solid solutions, which exhibited a change in character from tricritical towards second order of the cubic–tetragonal phase transition (Carpenter *et al.*, 2006). Landau analysis applied to the pressure-induced phase transition from the rutile to the $CaCl_2$-structured polymorph of stishovite showed that the strain energy increased progressively as a function of pressure above the transition pressure, a trend compatible with a second-order transition and a dominant symmetry-breaking strain component (Andrault *et al.*, 2003).

As well as changes at the crystal-structure scale, phase transitions modify the microstructure of materials (*e.g.* twin domains), leading to anomalous mesoscopic features at domain boundaries. One important consequence of twin mesostructures is their modified transport properties relative to the bulk. Landau theory also provides a tool for the analysis of microstructures and mesostructures in ferroelastics (Salje *et al.*, 2005). An example that illustrates the relevance of lattice strain to mass transport properties is the transition from the ferroelastic (monoclinic) to the paraelastic (orthorhombic) phase in the ZSM-5 zeolite (a synthetic analogue of the mineral mutinaite), which is a widely employed material in catalysis and water-treatment processes. The spontaneous-strain analysis *via* Landau theory of high-resolution synchrotron powder-diffraction data collected *in situ* upon heating allowed assessment of the tricritical character of the phase transition. This might favour the formation and persistence of ferroelastic domains on a local scale even in the paraelastic phase, thus explaining the unusual and unexpected deformation field distribution observed in monoclinic ZSM-5 crystals (Ardit *et al.*, 2015).

7.14.2.7. *HT studies related to CO_2 sequestration*

The growing concerns over increasing greenhouse-gas emissions and the need to reduce atmospheric carbon dioxide (CO_2) concentrations explains the growing number of studies devoted to the development of technologies for CO_2 sequestration into mineral form. The synthesis of minerals *via* the reaction of CO_2 with Mg–Ca silicate rocks, or of hydrated Mg carbonates in aqueous solutions, offers attractive solutions for permanent safe storage of CO_2. Consequently, interest in assessing the thermal stability of the best-suited mineral phases has induced a large number of *in situ* HT-XRPD studies. Carbonates are clearly the most studied candidates (*e.g.* Ballirano *et al.*, 2010; Morgan *et al.*, 2015; Merlini *et al.*, 2016). Based on HT studies it has been demonstrated that some carbonates (*e.g.* nesquehonite, $MgCO_3{\cdot}3H_2O$) remain stable under the prevalent temperature conditions on the Earth's surface, even if their stability is also influenced by factors like pH_2O and pCO_2. Understanding the factors that influence the stability of these phases opens a path for developing methods for CO_2 sequestration *via* the synthesis of carbonates for industrial applications.

7.14.3. Minerals related to human health, the biosphere and planetary exploration

7.14.3.1. *Fibrous minerals*

There has been a large and growing interest in recent years in the identification and distribution of minerals characterized by a fibrous habit.

Fibrous minerals are aggregates of slender fibres, parallel, interlaced or radiating, with the fibres usually separable. The term 'asbestiform' refers to a special type of fibrous habit in which a mineral has longitudinal parting and can be split into individual fibres and fibrils of high tensile strength, flexibility and minor thickness. The term 'asbestos' also indicates a number of natural silicates characterized by high surface reactivity and strong biopersistence. Asbestos comprises amphiboles [riebeckite, $Na_2Fe_2^{3+}(Fe^{2+},Mg)_3Si_8O_{22}(OH)_2$, grunerite, $Fe_2Fe_5Si_8O_{22}(OH)_2$, antophyllite, $Mg_2Mg_5[Si_8O_{22}](OH)_2$, tremolite, $Ca_2Mg_5Si_8O_{22}(OH)_2$, and actinolite, $Ca_2(Mg,Fe)_5Si_8O_{22}(OH)_2$] and phyllosilicates [chrysotile–serpentine $Mg_6Si_4O_{10}(OH)_8$]. The fibre characteristics, in particular the habit, of these minerals are very different (see Fig. 7.14.2). According to the mineralogical community, 'fibre' is a textural term indicating that the material looks like and, more importantly, behaves as a fibre, so that it can curve and bend under force (Rossi *et al.*, 2016, and references therein).

Although there is enough scientific evidence that asbestos when inhaled may induce malignant lung diseases (Guthrie & Mossman, 1993; Mossman *et al.*, 1990; Bignon *et al.*, 1996; Martuzzi *et al.*, 1998; Oury *et al.*, 2014; Mastrantonio *et al.*, 2002; Kamp, 2009), there is still controversy in ranking the carcinogenicity of chrysotile asbestos with respect to amphibole asbestos (Bernstein *et al.*, 2013). As a matter of fact, all amphibole asbestos minerals are banned worldwide, whereas chrysotile is banned only in those countries where the ruling of the International Agency for Research on Cancer (IARC) is accepted (Collegium Ramazzini, 2010; Gualtieri *et al.*, 2017).

Owing to the hazardous nature of asbestos, exposure to it represents a serious health risk. Therefore, the identification and quantification of asbestos in bulk materials is crucial. Along with microscopy, X-ray powder diffraction is considered a reliable tool for characterization of bulk materials. The Rietveld method has been successfully applied for the quantitative determination of asbestos in bulk materials such as insulating cements, mixed asbestos–slag wools, contaminated soil and others (Gualtieri, 1999). Analyses by XRPD are usually performed to identify other fibrous minerals that can be confused with asbestos (Bloise *et al.*, 2014). The potential hazard from asbestos to the health of

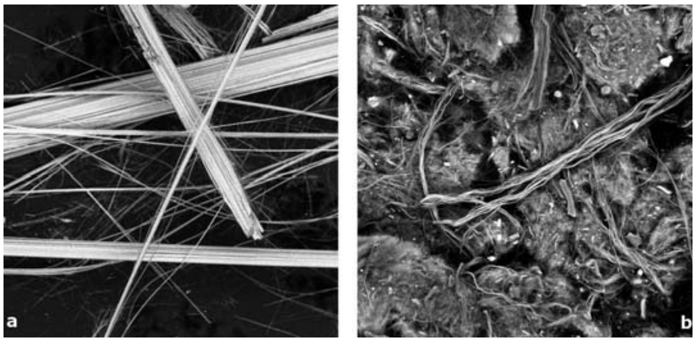

Figure 7.14.2
Habits of (*a*) amphibole asbestos (amosite) and (*b*) chrysotile asbestos. [Image courtesy of Professor Alessandro Gualtieri (University of Modena and Reggio Emilia, Italy) and Dr Alessandro Cavallo (University of Milano Bicocca, Italy)]

workers and public environmental issues during tunnel excavation in metamorphic formations, such as serpentinites, also require analytical procedures based on powder diffraction for an effective assessment of the presence of asbestos minerals (Ballirano *et al.*, 2008).

The elimination of asbestos-containing products from the environment has become a priority in many industrialized countries. It is now well established that asbestos-containing materials can be thermally transformed and recycled. In fact, when fired at temperatures higher than 1273 K, both serpentine or amphibole species transform into Mg–Fe silicates, which may be recycled at no cost in traditional ceramics (Gualtieri & Tartaglia, 2000). Thus, assessing the mechanism that controls the thermal decomposition of chrysotile at high temperatures has practical implications for the design of treatment plants and control of the firing processes of asbestos-containing materials.

Recently, research aimed at understanding the nature of the interaction of mineral fibres with biological systems and proposing a general model of fibre toxicity and/or pathogenicity has been carried out. The progress in synchrotron microdiffraction, μ-XRPD, allows improved understanding of the mechanisms of toxicity of these mineral fibres through the direct analyses of fibres found in the tissues of rats subjected to intraperitoneal/intrapleural injection of Union for International Cancer Control (UICC) chrysotile, UICC crocidolite and erionite-Na (Gualtieri *et al.*, 2017). The structural modifications observed through the collection of microdiffraction patterns, with special attention to the fibre crystallinity, allowed comparison of the biopersistence of the different phases, supporting the model of a lower biopersistence of chrysotile with respect to crocidolite; nevertheless, the formation of a silica-rich fibrous residue after the pseudo-amorphization of chrysotile could be responsible for the high cytotoxicity.

7.14.3.2. *Biominerals*

Biomineralization refers to the processes by which organisms form minerals and differentiates these phases from those formed by abiotic mineralization. The latter were the primary focus of Earth scientists over the last century, but the emergence of biogeochemistry and the urgent need to understand the past and future evolution of the Earth are moving biological mineralization into the forefront of various scientific fields, including the earth sciences (Weiner & Dove, 2003).

Furthermore, the study of biomaterials is a fascinating multidisciplinary field that crosses the boundary between basic and applied sciences. Knowledge of the mechanisms (fine-tuned by evolution over millions of years) used to produce materials perfectly fitting their functions enables development of new bio-inspired materials for use in modern technologies, such as bone implants or hybrid ceramic composites (Munch *et al.*, 2008; Xia & Jiang, 2008). Calcium carbonates are abundant building materials in nature (*e.g.* in mollusc shells, sea urchins and corals) and they also have many technological applications (*e.g.* as filler particles or coatings), making these minerals of great interest for biomimetic material synthesis. The mechanical properties of biominerals are often the result of a hierarchical construction employing organic components to regulate the precipitation of the inorganic phase (*e.g.* Mann, 2001). Recently, simple bio-inspired synthetic systems similar to biominerals were realized using charged polymer additives to induce hierarchical structuring of calcite, demonstrating how organic occlusions strongly affect the mechanism (Schenk *et al.*, 2012).

The advent of synchrotron radiation and the possibility of performing XRPD using micrometre and submicrometre spot sizes (μ-XRPD) represented a fundamental step for the study of these intriguing inhomogeneous, hierarchical materials. One of the first studies on biominerals was by DiMasi & Sarikaya (2004) on the orientation of crystals in the prismatic calcite layer and the nacre aragonite layer of a red abalone (Haliotis rufescens) shell. The exploitation of small-angle X-ray scattering (SAXS) (see Chapter 5.8) provides further information in the study of biominerals, such as grain size and shape. The coupling of μ-SAXS with μ-WAXS (wide-angle X-ray scattering) represents a powerful tool for investigating, for example, bone platelets. While μ-WAXS identifies the minerals and their crystallographic orientations in the bone, μ-SAXS reveals information about the morphology and orientation of the nanoplatelets. An example of the combined use of μ-SAXS and μ-WAXS was the investigation of bone formation in zebrafish, in which the authors observed a transition from amorphous to crystalline bone (Mahamid *et al.*, 2010).

7.14.3.3. *Mars mineralogy*

Curiosity and the other rovers (Sojourner, Spirit and Opportunity) have captured the public imagination since Sojourner safely landed on Mars in 1997. Although Sojourner and Spirit are no longer active, Curiosity still is (as of June 2018), providing a wealth of petrological, geochemical and mineralogical data that fascinate scientists and non-scientists alike. Curiosity landed at Gale Crater on 6 August 2012. The Mars Science Laboratory rover scooped samples of soil from the Rocknest Aeolian bedform in Gale Crater and the first non-terrestrial X-ray powder-diffraction pattern was collected. Analysis of the soil with the Chemistry & Mineralogy X-Ray Diffraction/X-Ray Fluorescence Instrument (CheMin) revealed the presence of plagioclase, forsteritic olivine, augite and pigeonite, with minor amounts of K-feldspar, magnetite, quartz, anhydrite, hematite and ilmenite (Bish *et al.*, 2014).

The use of μ-XRPD at synchrotron facilities is well known in the Earth sciences (Tamura & Kunz, 2015) and even hand-held X-ray powder diffractometers allowing identification of mineral phases in the field have been designed in the past, but only the miniature instrument of the Mars Science Laboratory (MSL; Sarrazin *et al.*, 2005) has attracted wide attention from scientists and the general public alike. The International Union of Crystallography (IUCr) and the International Astronomical Union sponsored the first International School/Workshop on Crystallography for Space Sciences organized by the Committee on Space Research (COSPAR), held in Puebla, Mexico, 17–29 April 2016. The aim of the workshop was to prepare participants for in-depth study of extra-terrestrial minerals, rocks and other interstellar particles, using *in situ* and remote analytical techniques.
